<b>1</b>	<b>Pascal Tokens</b>	<b>11</b>
1.1	Symbols . . . . .	11
1.2	Comments . . . . .	12
1.3	Reserved words . . . . .	13
1.3.1	Turbo Pascal reserved words . . . . .	13
1.3.2	Free Pascal reserved words . . . . .	14
1.3.3	Object Pascal reserved words . . . . .	14
1.3.4	Modifiers . . . . .	14
1.4	Identifiers . . . . .	15
1.5	Hint directives . . . . .	16
1.6	Numbers . . . . .	17
1.7	Labels . . . . .	18
1.8	Character strings . . . . .	18
<b>2</b>	<b>Constants</b>	<b>20</b>
2.1	Ordinary constants . . . . .	20
2.2	Typed constants . . . . .	21
2.3	Resource strings . . . . .	22
<b>3</b>	<b>Types</b>	<b>23</b>
3.1	Base types . . . . .	23
3.1.1	Ordinal types . . . . .	24
	Integers . . . . .	24
	Boolean types . . . . .	25
	Enumeration types . . . . .	26
	Subrange types . . . . .	27
3.1.2	Real types . . . . .	28
3.2	Character types . . . . .	28
3.2.1	Char or AnsiChar . . . . .	28
3.2.2	WideChar . . . . .	29
3.2.3	Other character types . . . . .	29

3.2.4	Strings	29
3.2.5	Short strings	29
3.2.6	Ansistrings	30
3.2.7	UnicodeStrings	32
3.2.8	WideStrings	32
3.2.9	Constant strings	33
3.2.10	PChar - Null terminated strings	33
3.2.11	String sizes	34
3.3	Structured Types	34
	Packed structured types	35
3.3.1	Arrays	36
	Static arrays	36
	Dynamic arrays	37
	Packing and unpacking an array	40
3.3.2	Record types	40
3.3.3	Set types	44
3.3.4	File types	45
3.4	Pointers	45
3.5	Forward type declarations	47
3.6	Procedural types	48
3.7	Variant types	51
3.7.1	Definition	51
3.7.2	Variants in assignments and expressions	52
3.7.3	Variants and interfaces	53
3.8	Type aliases	53
<b>4</b>	<b>Variables</b>	<b>56</b>
4.1	Definition	56

## About this guide

This document serves as the reference for the Pascal language as implemented by the Free Pascal compiler. It describes all Pascal constructs supported by Free Pascal, and lists all supported data types. It does not, however, give a detailed explanation of the Pascal language: it is not a tutorial. The aim is to list which Pascal constructs are supported, and to show where the Free Pascal implementation differs from the Turbo Pascal or Delphi implementations.

The Turbo Pascal and Delphi Pascal compilers introduced various features in the Pascal language. The Free Pascal compiler emulates these compilers in the appropriate mode of the compiler: certain features are available only if the compiler is switched to the appropriate mode. When required for a certain feature, the use of the `-M` command-line switch or `{ $MODE }` directive will be indicated in the text. More information about the various modes can be found in the user's manual and the programmer's manual.

Earlier versions of this document also contained the reference documentation of the `system` unit and `objpas` unit. This has been moved to the RTL reference guide.

## Notations

Throughout this document, we will refer to functions, types and variables with `typewriter` font. Files are referred to with a sans font: `filename`.

## Syntax diagrams

All elements of the Pascal language are explained in syntax diagrams. Syntax diagrams are like flow charts. Reading a syntax diagram means getting from the left side to the right side, following the arrows. When the right side of a syntax diagram is reached, and it ends with a single arrow, this means the syntax diagram is continued on the next line. If the line ends on 2 arrows pointing to each other, then the diagram is ended.

Syntactical elements are written like this

► syntactical elements are like this —————►

Keywords which must be typed exactly as in the diagram:

► **keywords are like this** —————►

When something can be repeated, there is an arrow around it:

► this can be repeated —————►

When there are different possibilities, they are listed in rows:

► First possibility —————►  
Second possibility

Note, that one of the possibilities can be empty:

► First possibility —————►  
Second possibility

This means that both the first or second possibility are optional. Of course, all these elements can be combined and nested.

## About the Pascal language

The language Pascal was originally designed by Niklaus Wirth around 1970. It has evolved significantly since that day, with a lot of contributions by the various compiler constructors (Notably: Borland). The basic elements have been kept throughout the years:

- Easy syntax, rather verbose, yet easy to read. Ideal for teaching.
- Strongly typed.
- Procedural.
- Case insensitive.
- Allows nested procedures.
- Easy input/output routines built-in.

The Turbo Pascal and Delphi Pascal compilers introduced various features in the Pascal language, most notably easier string handling and object orientedness. The Free Pascal compiler initially emulated most of Turbo Pascal and later on Delphi. It emulates these compilers in the appropriate mode of the compiler: certain features are available only if the compiler is switched to the appropriate mode. When required for a certain feature, the use of the `-M` command-line switch or `{ $MODE }` directive will be indicated in the text. More information about the various modes can be found in the user's manual and the programmer's manual.

# Chapter 1

## Pascal Tokens

Tokens are the basic lexical building blocks of source code: they are the 'words' of the language: characters are combined into tokens according to the rules of the programming language. There are five classes of tokens:

**reserved words** These are words which have a fixed meaning in the language. They cannot be changed or redefined.

**identifiers** These are names of symbols that the programmer defines. They can be changed and re-used. They are subject to the scope rules of the language.

**operators** These are usually symbols for mathematical or other operations: +, -, \* and so on.

**separators** This is usually white-space.

**constants** Numerical or character constants are used to denote actual values in the source code, such as 1 (integer constant) or 2.3 (float constant) or 'String constant' (a string: a piece of text).

In this chapter we describe all the Pascal reserved words, as well as the various ways to denote strings, numbers, identifiers etc.

### 1.1 Symbols

Free Pascal allows all characters, digits and some special character symbols in a Pascal source file.

The following characters have a special meaning:

+ - \* / = < > [ ] . , ( ) : ^ @ { } \$ # & %

and the following character pairs too:

<< >> \*\* <> >< <= >= := += -= \*= /= (\* \*) (. .) //

When used in a range specifier, the character pair ( . is equivalent to the left square bracket [. Likewise, the character pair . ) is equivalent to the right square bracket ]. When used for comment delimiters, the character pair ( \* is equivalent to the left brace { and the character pair \*) is equivalent to the right brace }. These character pairs retain their normal meaning in string expressions.

## 1.2 Comments

Comments are pieces of the source code which are completely discarded by the compiler. They exist only for the benefit of the programmer, so he can explain certain pieces of code. For the compiler, it is as if the comments were not present.

The following piece of code demonstrates a comment:

```
(* My beautiful function returns an interesting result *)
Function Beautiful : Integer;
```

The use of ( \* and \*) as comment delimiters dates from the very first days of the Pascal language. It has been replaced mostly by the use of { and } as comment delimiters, as in the following example:

```
{ My beautiful function returns an interesting result }
Function Beautiful : Integer;
```

The comment can also span multiple lines:

```
{
  My beautiful function returns an interesting result,
  but only if the argument A is less than B.
}
Function Beautiful (A,B : Integer): Integer;
```

Single line comments can also be made with the // delimiter:

```
// My beautiful function returns an interesting result
Function Beautiful : Integer;
```

The comment extends from the // character till the end of the line. This kind of comment was introduced by Borland in the Delphi Pascal compiler.

Free Pascal supports the use of nested comments. The following constructs are valid comments:

```
(* This is an old style comment *)
{ This is a Turbo Pascal comment }
// This is a Delphi comment. All is ignored till the end of the line.
```

The following are valid ways of nesting comments:

```
{ Comment 1 (* comment 2 *) }
(* Comment 1 { comment 2 } *)
{ comment 1 // Comment 2 }
(* comment 1 // Comment 2 *)
// comment 1 (* comment 2 *)
// comment 1 { comment 2 }
```

The last two comments *must* be on one line. The following two will give errors:

```
// Valid comment { No longer valid comment !!
}
```

and

```
// Valid comment (* No longer valid comment !!
*)
```

The compiler will react with a 'invalid character' error when it encounters such constructs, regardless of the -Mtp switch.

**Remark:** In TP and Delphi mode, nested comments are not allowed, for maximum compatibility with existing code for those compilers.

## 1.3 Reserved words

Reserved words are part of the Pascal language, and as such, cannot be redefined by the programmer. Throughout the syntax diagrams they will be denoted using a **bold** typeface. Pascal is not case sensitive so the compiler will accept any combination of upper or lower case letters for reserved words.

We make a distinction between Turbo Pascal and Delphi reserved words. In TP mode, only the Turbo Pascal reserved words are recognised, but the Delphi ones can be redefined. By default, Free Pascal recognises the Delphi reserved words.

### 1.3.1 Turbo Pascal reserved words

The following keywords exist in Turbo Pascal mode

absolute	file	object	string
and	for	of	then
array	function	operator	to
asm	goto	or	type
begin	if	packed	unit
case	implementation	procedure	until
const	in	program	uses
constructor	inherited	record	var
destructor	inline	reintroduce	while
div	interface	repeat	with
do	label	self	xor
downto	mod	set	
else	nil	shl	
end	not	shr	

### 1.3.2 Free Pascal reserved words

On top of the Turbo Pascal reserved words, Free Pascal also considers the following as reserved words:

dispose	false	true
exit	new	

### 1.3.3 Object Pascal reserved words

The reserved words of Object Pascal (used in Delphi or Objfpc mode) are the same as the Turbo Pascal ones, with the following additional keywords:

as	finalization	library	raise
class	finally	on	resourcestring
dispinterface	initialization	out	threadvar
except	inline	packed	try
exports	is	property	

### 1.3.4 Modifiers

The following is a list of all modifiers. They are not exactly reserved words in the sense that they can be used as identifiers, but in specific places, they have a special meaning for the compiler, i.e., the compiler considers them as part of the Pascal language.

absolute	export	nodefault	reintroduce
abstract	external	noreturn	result
alias	far	nostackframe	safecall
assembler	far16	oldfpccall	saveregisters
bitpacked	forward	otherwise	softfloat
break	generic	overload	specialize
cdecl	helper	override	static
continue	implements	pascal	stdcall
cppdecl	index	platform	stored
cvar	interrupt	private	strict
default	iochecks	protected	unaligned
deprecated	local	public	unimplemented
dynamic	message	published	varargs
enumerator	name	read	virtual
experimental	near	register	write

**Remark:** Predefined types such as `Byte`, `Boolean` and constants such as `maxint` are *not* reserved words. They are identifiers, declared in the system unit. This means that these types can be redefined in other units. The programmer is however not encouraged to do this, as it will cause a lot of confusion.

**Remark:** As of version 2.5.1 it is possible to use reserved words as identifiers by escaping them with a `&` sign. This means that the following is possible

```
var
  &var : integer;

begin
  &var:=1;
  Writeln(&var);
```

end.

however, it is not recommended to use this feature in new code, as it makes code less readable. It is mainly intended to fix old code when the list of reserved words changes and encompasses a word that was not yet reserved (See also section 1.4, page 15).

## 1.4 Identifiers

Identifiers denote programmer defined names for specific constants, types, variables, procedures and functions, units, and programs. All programmer defined names in the source code –excluding reserved words– are designated as identifiers.

Identifiers consist of between 1 and 127 significant characters (letters, digits and the underscore character), of which the first must be a letter (a-z or A-Z), or an underscore (\_). The following diagram gives the basic syntax for identifiers.

Like Pascal reserved words, identifiers are case insensitive, that is, both

```
myprocedure;
```

and

```
MyProcedure;
```

refer to the same procedure.

**Remark:** As of version 2.5.1 it is possible to specify a reserved word as an identifier by prepending it with an ampersand (&). This means that the following is possible:

```
program testdo;

procedure &do;

begin
end;

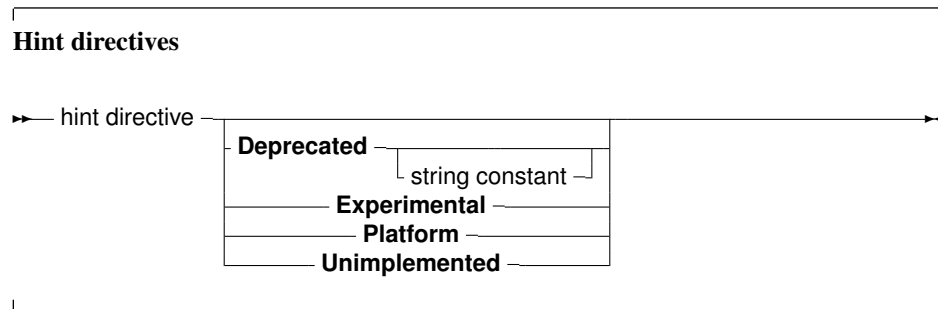

begin
  &do;
end.
```

The reserved word `do` is used as an identifier for the declaration as well as the invocation of the procedure `'do'`.

## 1.5 Hint directives

Most identifiers (constants, variables, functions or methods, properties) can have a hint directive appended to their definition:

Whenever an identifier marked with a hint directive is later encountered by the compiler, then a warning will be displayed, corresponding to the specified hint.

**deprecated** The use of this identifier is deprecated, use an alternative instead. The deprecated keyword can be followed by a string constant with a message. The compiler will show this message whenever the identifier is encountered.

**experimental** The use of this identifier is experimental: this can be used to flag new features that should be used with caution.

**platform** This is a platform-dependent identifier: it may not be defined on all platforms.

**unimplemented** This should be used on functions and procedures only. It should be used to signal that a particular feature has not yet been implemented.

The following are examples:

```

Const
  AConst = 12 deprecated;

var
  p : integer platform;

Function Something : Integer; experimental;

begin
  Something:=P+AConst;
end;

begin
  Something;
end.
  
```

This would result in the following output:

```

testhd.pp(11,15) Warning: Symbol "p" is not portable
testhd.pp(11,22) Warning: Symbol "AConst" is deprecated
testhd.pp(15,3) Warning: Symbol "Something" is experimental
  
```

Hint directives can follow all kinds of identifiers: units, constants, types, variables, functions, procedures and methods.

## 1.6 Numbers

Numbers are by default denoted in decimal notation. Real (or decimal) numbers are written using engineering or scientific notation (e.g. `0.314E1`).

For integer type constants, Free Pascal supports 4 formats:

1. Normal, decimal format (base 10). This is the standard format.
2. Hexadecimal format (base 16), in the same way as Turbo Pascal does. To specify a constant value in hexadecimal format, prepend it with a dollar sign (\$). Thus, the hexadecimal `$FF` equals 255 decimal. Note that case is insignificant when using hexadecimal constants.
3. As of version 1.0.7, Octal format (base 8) is also supported. To specify a constant in octal format, prepend it with an ampersand (&). For instance 15 is specified in octal notation as `&17`.
4. Binary notation (base 2). A binary number can be specified by preceding it with a percent sign (%). Thus, 255 can be specified in binary notation as `%11111111`.

The following diagrams show the syntax for numbers.

**Remark:** Octal and Binary notation are not supported in TP or Delphi compatibility mode.

## 1.7 Labels

A label is a name for a location in the source code to which can be jumped to from another location with a `goto` statement. A Label is a standard identifier or a digit sequence.

**Remark:** The `-Sg` or `-Mtp` switches must be specified before labels can be used. By default, Free Pascal doesn't support `label` and `goto` statements. The `{ $GOTO ON }` directive can also be used to allow use of labels and the `goto` statement.

The following are examples of valid labels:

```
Label
    123,
    abc;
```

## 1.8 Character strings

A character string (or string for short) is a sequence of zero or more characters (byte sized), enclosed in single quotes, and on a single line of the program source code: no literal carriage return or linefeed characters can appear in the string.

A character set with nothing between the quotes ( ' ' ) is an empty string.

The string consists of standard, 8-bit ASCII characters or Unicode (normally UTF-8 encoded) characters. The `control_string` can be used to specify characters which cannot be typed on a keyboard, such as `#27` for the escape character.

The single quote character can be embedded in the string by typing it twice. The C construct of escaping characters in the string (using a backslash) is not supported in Pascal.

The following are valid string constants:

```
'This is a pascal string'
''
'a'
'A tabulator character: '#9' is easy to embed'
```

The following is an invalid string:

```
'the string starts here
and continues here'
```

The above string must be typed as:

```
'the string starts here'#13#10'    and continues here'
```

or

```
'the string starts here'#10'    and continues here'
```

on unices (including Mac OS X), and as

```
'the string starts here'#13'    and continues here'
```

on a classic Mac-like operating system.

It is possible to use other character sets in strings: in that case the codepage of the source file must be specified with the `{ $CODEPAGE XXX }` directive or with the `-Fc` command line option for the compiler. In that case the characters in a string will be interpreted as characters from the specified codepage.

## Chapter 2

# Constants

Just as in Turbo Pascal, Free Pascal supports both ordinary and typed constants. They are declared in a constant declaration block in a unit, program or class, function or procedure declaration (section [16.4](#), page [198](#)).

### 2.1 Ordinary constants

Ordinary constants declarations are constructed using an identifier name followed by an "=" token, and followed by an optional expression consisting of legal combinations of numbers, characters, boolean values or enumerated values as appropriate. The following syntax diagram shows how to construct a legal declaration of an ordinary constant.

The compiler must be able to evaluate the expression in a constant declaration at compile time. This means that most of the functions in the Run-Time library cannot be used in a constant declaration. Operators such as `+`, `-`, `*`, `/`, `not`, `and`, `or`, `div`, `mod`, `ord`, `chr`, `sizeof`, `pi`, `int`, `trunc`, `round`, `frac`, `odd` can be used, however. For more information on expressions, see chapter [12](#), page [131](#).

Only constants of the following types can be declared:

- Ordinal types
- Set types
- Pointer types (but the only allowed value is `Nil`).
- Real types
- Char,
- String

The following are all valid constant declarations:

```
Const
  e = 2.7182818; { Real type constant. }
  a = 2;         { Ordinal (Integer) type constant. }
  c = '4';       { Character type constant. }
  s = 'This is a constant string'; {String type constant.}
  sc = chr(32)
  ls = SizeOf(Longint);
  P = Nil;
  Ss = [1,2];
```

Assigning a value to an ordinary constant is not permitted. Thus, given the previous declaration, the following will result in a compiler error:

```
s := 'some other string';
```

For string constants, the type of the string is dependent on some compiler switches. If a specific type is desired, a typed constant should be used, as explained in the following section.

Prior to version 1.9, Free Pascal did not correctly support 64-bit constants. As of version 1.9, 64-bit constants can be specified.

## 2.2 Typed constants

Sometimes it is necessary to specify the type of a constant, for instance for constants of complex structures (defined later in the manual). Their definition is quite simple.

Contrary to ordinary constants, a value can be assigned to them at run-time. This is an old concept from Turbo Pascal, which has been replaced with support for initialized variables: For a detailed description, see section 4.4, page 58.

Support for assigning values to typed constants is controlled by the `{ $J }` directive: it can be switched off, but is on by default (for Turbo Pascal compatibility). Initialized variables are always allowed.

**Remark:** It should be stressed that typed constants are automatically initialized at program start. This is also true for *local* typed constants and initialized variables. Local typed constants are also initialized at program start. If their value was changed during previous invocations of the function, they will retain their changed value, i.e. they are not initialized each time the function is invoked.

## 2.3 Resource strings

A special kind of constant declaration block is the `Resourcestring` block. `Resourcestring` declarations are much like constant string declarations: resource strings act as constant strings, but they can be localized by means of a set of special routines in the `objpas` unit. A resource string declaration block is only allowed in the `Delphi` or `Objfpc` modes.

The following is an example of a `resourcestring` definition:

```
Resourcestring

  FileMenu = '&File...';
  EditMenu = '&Edit...';
```

All string constants defined in the `resourcestring` section are stored in special tables. The strings in these tables can be manipulated at runtime with some special mechanisms in the `objpas` unit.

Semantically, the strings act like ordinary constants; It is not allowed to assign values to them (except through the special mechanisms in the `objpas` unit). However, they can be used in assignments or expressions as ordinary string constants. The main use of the `resourcestring` section is to provide an easy means of internationalization.

More on the subject of `resourcestrings` can be found in the [Programmer's Guide](#), and in the `objpas` unit reference.

**Remark:** Note that a resource string which is given as an expression will not change if the parts of the expression are changed:

```
resourcestring
  Part1 = 'First part of a long string.';
  Part2 = 'Second part of a long string.';
  Sentence = Part1+' '+Part2;
```

If the localization routines translate `Part1` and `Part2`, the `Sentence` constant will not be translated automatically: it has a separate entry in the resource string tables, and must therefore be translated separately. The above construct simply says that the initial value of `Sentence` equals `Part1+' '+Part2`.

**Remark:** Likewise, when using resource strings in a constant array, only the initial values of the resource strings will be used in the array: when the individual constants are translated, the elements in the array will retain their original value.

```
resourcestring
  Yes = 'Yes.';
  No = 'No.';

Var
  YesNo : Array[Boolean] of string = (No, Yes);
  B : Boolean;

begin
  Writeln(YesNo[B]);
end.
```

This will print 'Yes.' or 'No.' depending on the value of `B`, even if the constants `Yes` and `No` have been localized by some localization mechanism.

## Chapter 3

# Types

All variables have a type. Free Pascal supports the same basic types as Turbo Pascal, with some extra types from Delphi as well as some of its own.

The programmer can declare his own types, which is in essence defining an identifier that can be used to denote this custom type when declaring variables further in the source code.. Declaring a type happens in a `Type` block (section 16.4, page 198), which is a collection of type declarations, separated by semicolons:

There are 8 major kinds of types :

Each of these cases will be examined separately.

### 3.1 Base types

The base or simple types of Free Pascal are the Delphi types. We will discuss each type separately.

### 3.1.1 Ordinal types

With the exception of `int64`, `qword` and `Real` types, all base types are ordinal types. Ordinal types have the following characteristics:

1. Ordinal types are countable and ordered, i.e. it is, in principle, possible to start counting them one by one, in a specified order. This property allows the operation of functions as `Inc`, `Ord`, `Dec` on ordinal types to be defined.
2. Ordinal values have a smallest possible value. Trying to apply the `Pred` function on the smallest possible value will generate a range check error if range checking is enabled.
3. Ordinal values have a largest possible value. Trying to apply the `Succ` function on the largest possible value will generate a range check error if range checking is enabled.

#### Integers

A list of pre-defined integer types is presented in table (3.1).

Table 3.1: Predefined integer types

Name
Integer
Shortint
SmallInt
Longint
Longword
Int64
Byte
Word
Cardinal
QWord
Boolean
ByteBool
WordBool
LongBool
Char

The integer types, and their ranges and sizes, that are predefined in Free Pascal are listed in table (3.2). Please note that the `qword` and `int64` types are not true ordinals, so some Pascal constructs will not work with these two integer types.

Table 3.2: Predefined integer types

Type	Range	Size in bytes
Byte	0 .. 255	1
Shortint	-128 .. 127	1
Smallint	-32768 .. 32767	2
Word	0 .. 65535	2
Integer	either smallint or longint	size 2 or 4
Cardinal	longword	4
Longint	-2147483648 .. 2147483647	4
Longword	0 .. 4294967295	4
Int64	-9223372036854775808 .. 9223372036854775807	8
QWord	0 .. 18446744073709551615	8

The `integer` type maps to the `smallint` type in the default Free Pascal mode. It maps to either a `longint` in either Delphi or ObjFPC mode. The `cardinal` type is currently always mapped to the `longword` type.

**Remark:** All decimal constants which do not fit within the -2147483648..2147483647 range are silently and automatically parsed as 64-bit integer constants as of version 1.9.0. Earlier versions would convert it to a real-typed constant.

Free Pascal does automatic type conversion in expressions where different kinds of integer types are used.

### Boolean types

Free Pascal supports the `Boolean` type, with its two pre-defined possible values `True` and `False`. These are the only two values that can be assigned to a `Boolean` type. Of course, any expression that resolves to a `boolean` value, can also be assigned to a `boolean` type.

Table 3.3: Boolean types

Name	Size	Ord(True)
Boolean	1	1
ByteBool	1	Any nonzero value
WordBool	2	Any nonzero value
LongBool	4	Any nonzero value

Free Pascal also supports the `ByteBool`, `WordBool` and `LongBool` types. These are of type `Byte`, `Word` or `Longint`, but are assignment compatible with a `Boolean`: the value `False` is equivalent to 0 (zero) and any nonzero value is considered `True` when converting to a `boolean` value. A `boolean` value of `True` is converted to -1 in case it is assigned to a variable of type `LongBool`.

Assuming `B` to be of type `Boolean`, the following are valid assignments:

```
B := True;
B := False;
B := 1<>2; { Results in B := True }
```

Boolean expressions are also used in conditions.

**Remark:** In Free Pascal, boolean expressions are by default always evaluated in such a way that when the result is known, the rest of the expression will no longer be evaluated: this is called short-cut boolean evaluation.

In the following example, the function `Func` will never be called, which may have strange side-effects.

```
...
B := False;
A := B and Func;
```

Here `Func` is a function which returns a `Boolean` type.

This behaviour is controllable by the `{ $B }` compiler directive.

### Enumeration types

Enumeration types are supported in Free Pascal. On top of the Turbo Pascal implementation, Free Pascal allows also a C-style extension of the enumeration type, where a value is assigned to a particular element of the enumeration list.

(see chapter 12, page 131 for how to use expressions) When using assigned enumerated types, the assigned elements must be in ascending numerical order in the list, or the compiler will complain. The expressions used in assigned enumerated elements must be known at compile time. So the following is a correct enumerated type declaration:

```
Type
Direction = ( North, East, South, West );
```

A C-style enumeration type looks as follows:

```
Type
EnumType = (one, two, three, forty := 40, fortyone);
```

As a result, the ordinal number of `forty` is 40, and not 3, as it would be when the `' := 40 '` wasn't present. The ordinal value of `fortyone` is then 41, and not 4, as it would be when the assignment wasn't present. After an assignment in an enumerated definition the compiler adds 1 to the assigned value to assign to the next enumerated value.

When specifying such an enumeration type, it is important to keep in mind that the enumerated elements should be kept in ascending order. The following will produce a compiler error:

Type

```
EnumType = (one, two, three, forty := 40, thirty := 30);
```

It is necessary to keep `forty` and `thirty` in the correct order. When using enumeration types it is important to keep the following points in mind:

1. The `Pred` and `Succ` functions cannot be used on this kind of enumeration types. Trying to do this anyhow will result in a compiler error.
2. Enumeration types are stored using a default, independent of the actual number of values: the compiler does not try to optimize for space. This behaviour can be changed with the `{$PACKENUM n}` compiler directive, which tells the compiler the minimal number of bytes to be used for enumeration types. For instance

```
Type
{$PACKENUM 4}
  LargeEnum = ( BigOne, BigTwo, BigThree );
{$PACKENUM 1}
  SmallEnum = ( one, two, three );
Var S : SmallEnum;
    L : LargeEnum;
begin
  WriteLn ('Small enum : ', SizeOf(S));
  WriteLn ('Large enum : ', SizeOf(L));
end.
```

will, when run, print the following:

```
Small enum : 1
Large enum : 4
```

More information can be found in the [Programmer's Guide](#), in the compiler directives section.

### Subrange types

A subrange type is a range of values from an ordinal type (the *host* type). To define a subrange type, one must specify its limiting values: the highest and lowest value of the type.

#### Subrange types

➡ subrange type – constant – .. – constant ➡

Some of the predefined `integer` types are defined as subrange types:

Type

```
Longint  = $800000000..$7fffffff;
Integer  = -32768..32767;
shortint = -128..127;
byte     = 0..255;
Word     = 0..65535;
```

Subrange types of enumeration types can also be defined:

Type

```
Days = (monday, tuesday, wednesday, thursday, friday,
        saturday, sunday);
WorkDays = monday .. friday;
WeekEnd = Saturday .. Sunday;
```

### 3.1.2 Real types

Free Pascal uses the math coprocessor (or emulation) for all its floating-point calculations. The Real native type is processor dependent, but it is either Single or Double. Only the IEEE floating point types are supported, and these depend on the target processor and emulation options. The true Turbo Pascal compatible types are listed in table (3.4).

Table 3.4: Supported Real types

Type	Range	Significant digits	Size
Real	platform dependant	???	4 or 8
Single	1.5E-45 .. 3.4E38	7-8	4
Double	5.0E-324 .. 1.7E308	15-16	8
Extended	1.9E-4932 .. 1.1E4932	19-20	10
Comp	-2E64+1 .. 2E63-1	19-20	8
Currency	-922337203685477.5808 .. 922337203685477.5807	19-20	8

The `Comp` type is, in effect, a 64-bit integer and is not available on all target platforms. To get more information on the supported types for each platform, refer to the [Programmer's Guide](#).

The currency type is a fixed-point real data type which is internally used as an 64-bit integer type (automatically scaled with a factor 10000), this minimalizes rounding errors.

## 3.2 Character types

### 3.2.1 Char or AnsiChar

Free Pascal supports the type `Char`. A `Char` is exactly 1 byte in size, and contains one ASCII character.

A character constant can be specified by enclosing the character in single quotes, as follows : 'a' or 'A' are both character constants.

A character can also be specified by its character value (commonly an ASCII code), by preceding the ordinal value with the number symbol (#). For example specifying #65 would be the same as 'A'.

Also, the caret character (^) can be used in combination with a letter to specify a character with ASCII value less than 27. Thus ^G equals #7 - G is the seventh letter in the alphabet. The compiler is rather sloppy about the characters it allows after the caret, but in general one should assume only letters.

When the single quote character must be represented, it should be typed two times successively, thus ''' represents the single quote character.

To distinguish `Char` from `WideChar`, the system unit also defines the `AnsiChar` type, which is the same as the `char` type. In future versions of FPC, the `Char` type may become an alias for either `WideChar` or `AnsiChar`.

### 3.2.2 WideChar

Free Pascal supports the type `WideChar`. A `WideChar` is exactly 2 bytes in size, and contains one UNICODE character in UTF-16 encoding.

A unicode character can be specified by its character value (an UTF-16 code), by preceding the ordinal value with the number symbol (#).

A normal ansi (1-byte) character literal can also be used for a widechar, the compiler will automatically convert it to a 2-byte UTF-16 character.

The following defines some greek characters (phi, omega):

```
Const
  C3 : widechar = #$03A8;
  C4 : widechar = #$03A9;
```

The same can be accomplished by typecasting a word to widechar:

```
Const
  C3 : widechar = widechar($03A8);
  C4 : widechar = widechar($03A9);
```

### 3.2.3 Other character types

Free Pascal defines some other character types in the system unit such as `UCS2Char`, `UCS4Char`, `UniCodeChar`. However, no special support for these character types exists, they have been defined for Delphi compatibility only.

### 3.2.4 Strings

Free Pascal supports the `String` type as it is defined in Turbo Pascal: a sequence of characters with an optional size specification. It also supports ansistrings (with unlimited length) as in Delphi.

To declare a variable as a string, use the following type specification:

If there is a size specifier, then its maximum value - indicating the maximum size of the string - is 255.

The meaning of a string declaration statement without size indicator is interpreted differently depending on the `{ $H }` switch. If no size indication is present, the above declaration can declare an ansistring or a short string.

Whatever the actual type, ansistrings and short strings can be used interchangeably. The compiler always takes care of the necessary type conversions. Note, however, that the result of an expression that contains ansistrings and short strings will always be an ansistring.

### 3.2.5 Short strings

A string declaration declares a short string in the following cases:

1. If the switch is off: `{ $H- }`, the string declaration will always be a short string declaration.
2. If the switch is on `{ $H+ }`, and there is a maximum length (the size) specifier, the declaration is a short string declaration.

The predefined type `ShortString` is defined as a string of size 255:

```
ShortString = String[255];
```

If the size of the string is not specified, 255 is taken as a default. The actual length of the string can be obtained with the `Length` standard runtime routine. For example in

```
{ $H- }
```

Type

```
NameString = String[10];
StreetString = String;
```

`NameString` can contain a maximum of 10 characters. While `StreetString` can contain up to 255 characters.

**Remark:** Short strings have a maximum length of 255 characters: when specifying a maximum length, the maximum length may not exceed 255. If a length larger than 255 is attempted, then the compiler will give an error message:

```
Error: string length must be a value from 1 to 255
```

For short strings, the length is stored in the character at index 0. Old Turbo Pascal code relies on this, and it is implemented similarly in Free Pascal. Despite this, to write portable code, it is best to set the length of a shortstring with the `SetLength` call, and to retrieve it with the `Length` call. These functions will always work, whatever the internal representation of the shortstrings or other strings in use: this allows easy switching between the various string types.

### 3.2.6 Ansistrings

Ansistrings are strings that have no length limit. They are reference counted and are guaranteed to be null terminated. Internally, an ansistring is treated as a pointer: the actual content of the string is stored on the heap, as much memory as needed to store the string content is allocated.

This is all handled transparently, i.e. they can be manipulated as a normal short string. Ansistrings can be defined using the predefined `AnsiString` type.

**Remark:** The null-termination does not mean that null characters (`char(0)` or `#0`) cannot be used: the null-termination is not used internally, but is there for convenience when dealing with external routines that expect a null-terminated string (as most C routines do).

If the `{ $H }` switch is on, then a string definition using the regular `String` keyword and that doesn't contain a length specifier, will be regarded as an ansistring as well. If a length specifier is present, a short string will be used, regardless of the `{ $H }` setting.

If the string is empty (`""`), then the internal pointer representation of the string pointer is `Nil`. If the string is not empty, then the pointer points to a structure in heap memory.

The internal representation as a pointer, and the automatic null-termination make it possible to type-cast an ansistring to a `pchar`. If the string is empty (so the pointer is `Nil`) then the compiler makes sure that the typecasted `pchar` will point to a null byte.

Assigning one ansistring to another doesn't involve moving the actual string. A statement

```
S2:=S1;
```

results in the reference count of S2 being decreased with 1, The reference count of S1 is increased by 1, and finally S1 (as a pointer) is copied to S2. This is a significant speed-up in the code.

If the reference count of a string reaches zero, then the memory occupied by the string is deallocated automatically, and the pointer is set to Nil, so no memory leaks arise.

When an ansistring is declared, the Free Pascal compiler initially allocates just memory for a pointer, not more. This pointer is guaranteed to be Nil, meaning that the string is initially empty. This is true for local and global ansistrings or ansistrings that are part of a structure (arrays, records or objects).

This does introduce an overhead. For instance, declaring

```
Var
  A : Array[1..100000] of string;
```

Will copy the value Nil 100,000 times into A. When A goes out of scope, then the reference count of the 100,000 strings will be decreased by 1 for each of these strings. All this happens invisible to the programmer, but when considering performance issues, this is important.

Memory for the string content will be allocated only when the string is assigned a value. If the string goes out of scope, then its reference count is automatically decreased by 1. If the reference count reaches zero, the memory reserved for the string is released.

If a value is assigned to a character of a string that has a reference count greater than 1, such as in the following statements:

```
S:=T; { reference count for S and T is now 2 }
S[I]:='@';
```

then a copy of the string is created before the assignment. This is known as *copy-on-write* semantics. It is possible to force a string to have reference count equal to 1 with the UniqueString call:

```
S:=T;
R:=T; // Reference count of T is at least 3
UniqueString(T);
// Reference count of T is guaranteed 1
```

It's recommended to do this e.g. when typecasting an ansistring to a PChar var and passing it to a C routine that modifies the string.

The Length function must be used to get the length of an ansistring: the length is not stored at character 0 of the ansistring. The construct

```
L:=ord(S[0]);
```

which was valid for Turbo Pascal shortstrings, is no longer correct for Ansistrings. The compiler will warn if such a construct is encountered.

To set the length of an ansistring, the SetLength function must be used. Constant ansistrings have a reference count of -1 and are treated specially, The same remark as for Length must be given: The construct

```
L:=12;
S[0]:=Char(L);
```

which was valid for Turbo Pascal shortstrings, is no longer correct for Ansistrings. The compiler will warn if such a construct is encountered.

Ansistrings are converted to short strings by the compiler if needed, this means that the use of ansistrings and short strings can be mixed without problems.

Ansistrings can be typecasted to `PChar` or `Pointer` types:

```
Var P : Pointer;
    PC : PChar;
    S : AnsiString;

begin
  S := 'This is an ansistring';
  PC := PChar(S);
  P := Pointer(S);
```

There is a difference between the two typecasts. When an empty ansistring is typecasted to a pointer, the pointer will be `Nil`. If an empty ansistring is typecasted to a `PChar`, then the result will be a pointer to a zero byte (an empty string).

The result of such a typecast must be used with care. In general, it is best to consider the result of such a typecast as read-only, i.e. only suitable for passing to a procedure that needs a constant `pchar` argument.

It is therefore *not* advisable to typecast one of the following:

1. Expressions.
2. Strings that have reference count larger than 1. In this case you should call `Uniquestring` to ensure the string has reference count 1.

### 3.2.7 UnicodeStrings

Unicodestrings (used to represent unicode character strings) are implemented in much the same way as ansistrings: reference counted, null-terminated arrays, only they are implemented as arrays of `WideChars` instead of regular `Chars`. A `WideChar` is a two-byte character (an element of a DBCS: Double Byte Character Set). Mostly the same rules apply for `UnicodeStrings` as for `AnsiStrings`. The compiler transparently converts `UnicodeStrings` to `AnsiStrings` and vice versa.

Similarly to the typecast of an `AnsiString` to a `PChar` null-terminated array of characters, a `UnicodeString` can be converted to a `PUnicodeChar` null-terminated array of characters. Note that the `PUnicodeChar` array is terminated by 2 null bytes instead of 1, so a typecast to a `pchar` is not automatic.

The compiler itself provides no support for any conversion from Unicode to ansistrings or vice versa. The `system` unit has a `unicodestring` manager record, which can be initialized with some OS-specific unicode handling routines. For more information, see the `system` unit reference.

A unicode string literal can be constructed in a similar manner as a `widechar`:

```
Const
  ws2: unicodestring = 'phi omega : ' # $03A8 ' ' # $03A9;
```

### 3.2.8 WideStrings

Widestrings (used to represent unicode character strings in COM applications) are implemented in much the same way as `unicodestrings`. Unlike the latter, they are *not* reference counted, and on Windows, they are allocated with a special windows function which allows them to be used for OLE

automation. This means they are implemented as null-terminated arrays of `WideChars` instead of regular `Chars`. Mostly the same rules apply for `WideStrings` as for `AnsiStrings`. Similar to `unicodestrings`, the compiler transparently converts `WideStrings` to `AnsiStrings` and vice versa.

For typecasting and conversion, the same rules apply as for the `unicodestring` type.

### 3.2.9 Constant strings

To specify a constant string, it must be enclosed in single-quotes, just as a `Char` type, only now more than one character is allowed. Given that `S` is of type `String`, the following are valid assignments:

```
S := 'This is a string.';
S := 'One'+' ', 'Two'+' ', 'Three';
S := 'This isn't difficult !';
S := 'This is a weird character : '#145' !';
```

As can be seen, the single quote character is represented by 2 single-quote characters next to each other. Strange characters can be specified by their character value (usually an ASCII code). The example shows also that two strings can be added. The resulting string is just the concatenation of the first with the second string, without spaces in between them. Strings can not be subtracted, however.

Whether the constant string is stored as an `ansistring` or a short string depends on the settings of the `{H}` switch.

### 3.2.10 PChar - Null terminated strings

Free Pascal supports the Delphi implementation of the `PChar` type. `PChar` is defined as a pointer to a `Char` type, but allows additional operations. The `PChar` type can be understood best as the Pascal equivalent of a C-style null-terminated string, i.e. a variable of type `PChar` is a pointer that points to an array of type `Char`, which is ended by a null-character (`#0`). Free Pascal supports initializing of `PChar` typed constants, or a direct assignment. For example, the following pieces of code are equivalent:

```
program one;
var P : PChar;
begin
  P := 'This is a null-terminated string.';
  WriteLn (P);
end.
```

Results in the same as

```
program two;
const P : PChar = 'This is a null-terminated string.';
begin
  WriteLn (P);
end.
```

These examples also show that it is possible to write *the contents* of the string to a file of type `Text`. The `strings` unit contains procedures and functions that manipulate the `PChar` type as in the standard C library. Since it is equivalent to a pointer to a type `Char` variable, it is also possible to do the following:

```

Program three;
Var S : String[30];
    P : PChar;
begin
  S := 'This is a null-terminated string.'#0;
  P := @S[1];
  WriteLn (P);
end.

```

This will have the same result as the previous two examples. Null-terminated strings cannot be added as normal Pascal strings. If two `PChar` strings must be concatenated; the functions from the unit `strings` must be used.

However, it is possible to do some pointer arithmetic. The operators `+` and `-` can be used to do operations on `PChar` pointers. In table (3.5), `P` and `Q` are of type `PChar`, and `I` is of type `Longint`.

Table 3.5: `PChar` pointer arithmetic

Operation	Result
<code>P + I</code>	Adds <code>I</code> to the address pointed to by <code>P</code> .
<code>I + P</code>	Adds <code>I</code> to the address pointed to by <code>P</code> .
<code>P - I</code>	Subtracts <code>I</code> from the address pointed to by <code>P</code> .
<code>P - Q</code>	Returns, as an integer, the distance between 2 addresses (or the number of characters between <code>P</code> and <code>Q</code> )

### 3.2.11 String sizes

The memory occupied by a string depends on the string type. Some string types allocate the string data in memory on the heap, others have the string data on the stack. Table (3.6) summarizes the memory usage of the various string types for the various string types. In the table, `HeaderSize` depends on the version of Free Pascal, but is 16 bytes as of Free Pascal 2.7.1. `L` is the actual length of the string.

Table 3.6: String memory sizes

String type	Stack size	heap size
<code>Shortstring</code>	Declared length + 2	0
<code>Ansistring</code>	Pointer size	<code>L + 1 + HeaderSize</code>
<code>Widestring</code>	Pointer size	<code>2*L + 1 + HeaderSize</code> (0 on Windows)
<code>UnicodeString</code>	Pointer size	<code>2*L + 1 + HeaderSize</code>
<code>Pchar</code>	Pointer size	<code>L+1</code>

## 3.3 Structured Types

A structured type is a type that can hold multiple values in one variable. Structured types can be nested to unlimited levels.

### Structured Types

Unlike Delphi, Free Pascal does not support the keyword `Packed` for all structured types. In the following sections each of the possible structured types is discussed. It will be mentioned when a type supports the `packed` keyword.

### Packed structured types

When a structured type is declared, no assumptions should be made about the internal position of the elements in the type. The compiler will lay out the elements of the structure in memory as it thinks will be most suitable. That is, the order of the elements will be kept, but the location of the elements are not guaranteed, and is partially governed by the `$PACKRECORDS` directive (this directive is explained in the [Programmer's Guide](#)).

However, Free Pascal allows controlling the layout with the `Packed` and `Bitpacked` keywords. The meaning of these words depends on the context:

**Bitpacked** In this case, the compiler will attempt to align ordinal types on bit boundaries, as explained below.

**Packed** The meaning of the `Packed` keyword depends on the situation:

1. In MACPAS mode, it is equivalent to the `Bitpacked` keyword.
2. In other modes, with the `$BITPACKING` directive set to `ON`, it is also equivalent to the `Bitpacked` keyword.
3. In other modes, with the `$BITPACKING` directive set to `OFF`, it signifies normal packing on byte boundaries.

Packing on byte boundaries means that each new element of a structured type starts on a byte boundary.

The byte packing mechanism is simple: the compiler aligns each element of the structure on the first available byte boundary, even if the size of the previous element (small enumerated types, subrange types) is less than a byte.

When using the bit packing mechanism, the compiler calculates for each ordinal type how many bits are needed to store it. The next ordinal type is then stored on the next free bit. Non-ordinal types - which include but are not limited to - sets, floats, strings, (bitpacked) records, (bitpacked) arrays, pointers, classes, objects, and procedural variables, are stored on the first available byte boundary.

Note that the internals of the bitpacking are opaque: they can change at any time in the future. What is more: the internal packing depends on the endianness of the platform for which the compilation is done, and no conversion between platforms are possible. This makes bitpacked structures unsuitable for storing on disk or transport over networks. The format is however the same as the one used by the GNU Pascal Compiler, and the Free Pascal team aims to retain this compatibility in the future.

There are some more restrictions to elements of bitpacked structures:

- The address cannot be retrieved, unless the bit size is a multiple of 8 and the element happens to be stored on a byte boundary.

- An element of a bitpacked structure cannot be used as a var parameter, unless the bit size is a multiple of 8 and the element happens to be stored on a byte boundary.

To determine the size of an element in a bitpacked structure, there is the `BitSizeOf` function. It returns the size - in bits - of the element. For other types or elements of structures which are not bitpacked, this will simply return the size in bytes multiplied by 8, i.e., the return value is then the same as `8*SizeOf`.

The size of bitpacked records and arrays is limited:

- On 32 bit systems the maximal size is  $2^{29}$  bytes (512 MB).
- On 64 bit systems the maximal size is  $2^{61}$  bytes.

The reason is that the offset of an element must be calculated with the maximum integer size of the system.

### 3.3.1 Arrays

Free Pascal supports arrays as in Turbo Pascal. Multi-dimensional arrays and (bit)packed arrays are also supported, as well as the dynamic arrays of Delphi:

#### Static arrays

When the range of the array is included in the array definition, it is called a static array. Trying to access an element with an index that is outside the declared range will generate a run-time error (if range checking is on). The following is an example of a valid array declaration:

```
Type
  RealArray = Array [1..100] of Real;
```

Valid indexes for accessing an element of the array are between 1 and 100, where the borders 1 and 100 are included. As in Turbo Pascal, if the array component type is in itself an array, it is possible to combine the two arrays into one multi-dimensional array. The following declaration:

```
Type
  APoints = array[1..100] of Array[1..3] of Real;
```

is equivalent to the declaration:

```
Type
  APoints = array[1..100,1..3] of Real;
```

The functions `High` and `Low` return the high and low bounds of the leftmost index type of the array. In the above case, this would be 100 and 1. You should use them whenever possible, since it improves

maintainability of your code. The use of both functions is just as efficient as using constants, because they are evaluated at compile time.

When static array-type variables are assigned to each other, the contents of the whole array is copied. This is also true for multi-dimensional arrays:

```
program testarray1;

Type
  TA = Array[0..9,0..9] of Integer;

var
  A,B : TA;
  I,J : Integer;
begin
  For I:=0 to 9 do
    For J:=0 to 9 do
      A[I,J]:=I*J;
  For I:=0 to 9 do
    begin
      For J:=0 to 9 do
        Write(A[I,J]:2,' ');
      Writeln;
    end;
  B:=A;
  Writeln;
  For I:=0 to 9 do
    For J:=0 to 9 do
      A[9-I,9-J]:=I*J;
  For I:=0 to 9 do
    begin
      For J:=0 to 9 do
        Write(B[I,J]:2,' ');
      Writeln;
    end;
end.
```

The output of this program will be 2 identical matrices.

### Dynamic arrays

As of version 1.1, Free Pascal also knows dynamic arrays: In that case the array range is omitted, as in the following example:

```
Type
  TByteArray = Array of Byte;
```

When declaring a variable of a dynamic array type, the initial length of the array is zero. The actual length of the array must be set with the standard `SetLength` function, which will allocate the necessary memory to contain the array elements on the heap. The following example will set the length to 1000:

```
Var
  A : TByteArray;
```

```
begin
  SetLength(A, 1000);
```

After a call to `SetLength`, valid array indexes are 0 to 999: the array index is always zero-based.

Note that the length of the array is set in elements, not in bytes of allocated memory (although these may be the same). The amount of memory allocated is the size of the array multiplied by the size of 1 element in the array. The memory will be disposed of at the exit of the current procedure or function.

It is also possible to resize the array: in that case, as much of the elements in the array as will fit in the new size, will be kept. The array can be resized to zero, which effectively resets the variable.

At all times, trying to access an element of the array with an index that is not in the current length of the array will generate a run-time error.

Dynamic arrays are reference counted: assignment of one dynamic array-type variable to another will let both variables point to the same array. Contrary to `ansistring`s, an assignment to an element of one array will be reflected in the other: there is no copy-on-write. Consider the following example:

```
Var
  A, B : TArray;

begin
  SetLength(A, 10);
  A[0] := 33;
  B := A;
  A[0] := 31;
```

After the second assignment, the first element in `B` will also contain 31.

It can also be seen from the output of the following example:

```
program testarray1;

Type
  TA = Array of array of Integer;

var
  A, B : TA;
  I, J : Integer;
begin
  Setlength(A, 10, 10);
  For I:=0 to 9 do
    For J:=0 to 9 do
      A[I, J] := I * J;
  For I:=0 to 9 do
    begin
      For J:=0 to 9 do
        Write(A[I, J]:2, ' ');
      Writeln;
    end;
  B := A;
  Writeln;
  For I:=0 to 9 do
    For J:=0 to 9 do
```

```
        A[9-I, 9-J] := I*J;
For I:=0 to 9 do
begin
  For J:=0 to 9 do
    Write(B[I, J]:2, ' ');
  Writeln;
end;
end.
```

The output of this program will be a matrix of numbers, and then the same matrix, mirrored.

As remarked earlier, dynamic arrays are reference counted: if in one of the previous examples A goes out of scope and B does not, then the array is not yet disposed of: the reference count of A (and B) is decreased with 1. As soon as the reference count reaches zero the memory, allocated for the contents of the array, is disposed of.

The `SetLength` call will make sure the reference count of the returned array is 1, that is, if 2 dynamic array variables were pointing to the same memory they will no longer do so after the `setlength` call:

```
program testunique;

Type
  TA = array of Integer;

var
  A, B : TA;
  I : Integer;

begin
  Setlength(A, 10);
  For I:=0 to 9 do
    A[I] := I;
  B := A;
  SetLength(B, 6);
  A[0] := 123;
  For I:=0 to 5 do
    Writeln(B[I]);
end.
```

It is also possible to copy and/or resize the array with the standard `Copy` function, which acts as the copy function for strings:

```
program testarray3;

Type
  TA = array of Integer;

var
  A, B : TA;
  I : Integer;

begin
  Setlength(A, 10);
  For I:=0 to 9 do
```

```

    A[I]:=I;
  B:=Copy(A,3,6);
  For I:=0 to 5 do
    Writeln(B[I]);
  end.

```

The `Copy` function will copy 6 elements of the array to a new array. Starting at the element at index 3 (i.e. the fourth element) of the array.

The `Length` function will return the number of elements in the array. The `Low` function on a dynamic array will always return 0, and the `High` function will return the value `Length-1`, i.e., the value of the highest allowed array index.

### Packing and unpacking an array

Arrays can be packed and bitpacked. 2 array types which have the same index type and element type, but which are differently packed are not assignment compatible.

However, it is possible to convert a normal array to a bitpacked array with the `pack` routine. The reverse operation is possible as well; a bitpacked array can be converted to a normally packed array using the `unpack` routine, as in the following example:

```

Var
  foo : array [ 'a'..'f' ] of Boolean
    = ( false, false, true, false, false, false );
  bar : packed array [ 42..47 ] of Boolean;
  baz : array [ '0'..'5' ] of Boolean;

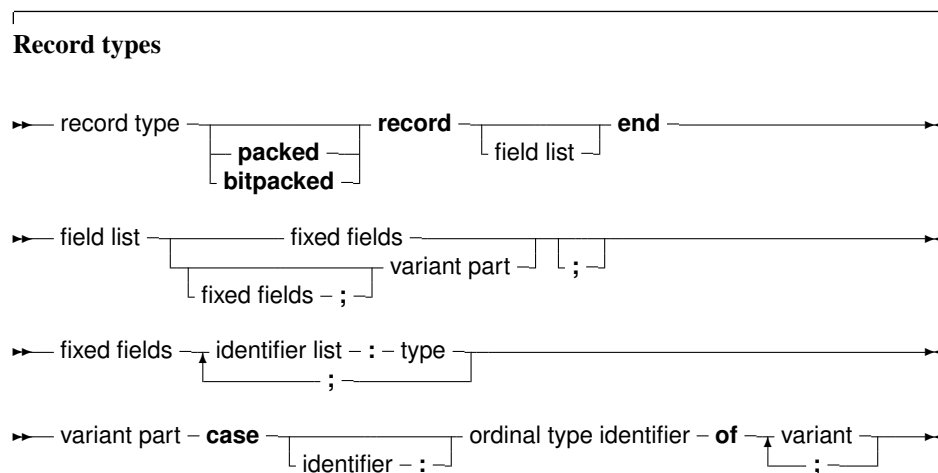

begin
  pack(foo,'a',bar);
  unpack(bar,baz,'0');
end.

```

More information about the `pack` and `unpack` routines can be found in the `system` unit reference.

## 3.3.2 Record types

Free Pascal supports fixed records and records with variant parts. The syntax diagram for a record type is

So the following are valid record type declarations:

```
Type
  Point = Record
    X, Y, Z : Real;
  end;
  RPoint = Record
    Case Boolean of
      False : (X, Y, Z : Real);
      True  : (R, theta, phi : Real);
    end;
  BetterRPoint = Record
    Case UsePolar : Boolean of
      False : (X, Y, Z : Real);
      True  : (R, theta, phi : Real);
    end;
```

The variant part must be last in the record. The optional identifier in the case statement serves to access the tag field value, which otherwise would be invisible to the programmer. It can be used to see which variant is active at a certain time<sup>1</sup>. In effect, it introduces a new field in the record.

**Remark:** It is possible to nest variant parts, as in:

```
Type
  MyRec = Record
    X : Longint;
    Case byte of
      2 : (Y : Longint;
          case byte of
            3 : (Z : Longint);
          );
    end;
```

By default the size of a record is the sum of the sizes of its fields, each size of a field is rounded up to a power of two. If the record contains a variant part, the size of the variant part is the size of the biggest variant, plus the size of the tag field type *if an identifier was declared for it*. Here also, the size of each part is first rounded up to two. So in the above example:

- SizeOf would return 24 for Point,
- It would result in 24 for RPoint
- Finally, 26 would be the size of BetterRPoint.
- For MyRec, the value would be 12.

If a typed file with records, produced by a Turbo Pascal program, must be read, then chances are that attempting to read that file correctly will fail. The reason for this is that by default, elements of a record are aligned at 2-byte boundaries, for performance reasons.

<sup>1</sup>However, it is up to the programmer to maintain this field.

This default behaviour can be changed with the `{$PACKRECORDS N}` switch. Possible values for `N` are 1, 2, 4, 16 or `Default`. This switch tells the compiler to align elements of a record or object or class that have size larger than `n` on `n` byte boundaries.

Elements that have size smaller or equal than `n` are aligned on natural boundaries, i.e. to the first power of two that is larger than or equal to the size of the record element.

The keyword `Default` selects the default value for the platform that the code is compiled for (currently, this is 2 on all platforms) Take a look at the following program:

```
Program PackRecordsDemo;
type
  {$PackRecords 2}
  Trec1 = Record
    A : byte;
    B : Word;
  end;

  {$PackRecords 1}
  Trec2 = Record
    A : Byte;
    B : Word;
  end;
  {$PackRecords 2}
  Trec3 = Record
    A,B : byte;
  end;

  {$PackRecords 1}
  Trec4 = Record
    A,B : Byte;
  end;
  {$PackRecords 4}
  Trec5 = Record
    A : Byte;
    B : Array[1..3] of byte;
    C : byte;
  end;

  {$PackRecords 8}
  Trec6 = Record
    A : Byte;
    B : Array[1..3] of byte;
    C : byte;
  end;
  {$PackRecords 4}
  Trec7 = Record
    A : Byte;
    B : Array[1..7] of byte;
    C : byte;
  end;

  {$PackRecords 8}
  Trec8 = Record
    A : Byte;
```

```

        B : Array[1..7] of byte;
        C : byte;
    end;
Var rec1 : Trec1;
    rec2 : Trec2;
    rec3 : Trec3;
    rec4 : Trec4;
    rec5 : Trec5;
    rec6 : Trec6;
    rec7 : Trec7;
    rec8 : Trec8;

begin
    Write ('Size Trec1 : ', SizeOf(Trec1));
    Writeln (' Offset B : ', Longint (@rec1.B) - Longint (@rec1));
    Write ('Size Trec2 : ', SizeOf(Trec2));
    Writeln (' Offset B : ', Longint (@rec2.B) - Longint (@rec2));
    Write ('Size Trec3 : ', SizeOf(Trec3));
    Writeln (' Offset B : ', Longint (@rec3.B) - Longint (@rec3));
    Write ('Size Trec4 : ', SizeOf(Trec4));
    Writeln (' Offset B : ', Longint (@rec4.B) - Longint (@rec4));
    Write ('Size Trec5 : ', SizeOf(Trec5));
    Writeln (' Offset B : ', Longint (@rec5.B) - Longint (@rec5),
            ' Offset C : ', Longint (@rec5.C) - Longint (@rec5));
    Write ('Size Trec6 : ', SizeOf(Trec6));
    Writeln (' Offset B : ', Longint (@rec6.B) - Longint (@rec6),
            ' Offset C : ', Longint (@rec6.C) - Longint (@rec6));
    Write ('Size Trec7 : ', SizeOf(Trec7));
    Writeln (' Offset B : ', Longint (@rec7.B) - Longint (@rec7),
            ' Offset C : ', Longint (@rec7.C) - Longint (@rec7));
    Write ('Size Trec8 : ', SizeOf(Trec8));
    Writeln (' Offset B : ', Longint (@rec8.B) - Longint (@rec8),
            ' Offset C : ', Longint (@rec8.C) - Longint (@rec8));
end.

```

The output of this program will be :

```

Size Trec1 : 4 Offset B : 2
Size Trec2 : 3 Offset B : 1
Size Trec3 : 2 Offset B : 1
Size Trec4 : 2 Offset B : 1
Size Trec5 : 8 Offset B : 4 Offset C : 7
Size Trec6 : 8 Offset B : 4 Offset C : 7
Size Trec7 : 12 Offset B : 4 Offset C : 11
Size Trec8 : 16 Offset B : 8 Offset C : 15

```

And this is as expected:

- In Trec1, since B has size 2, it is aligned on a 2 byte boundary, thus leaving an empty byte between A and B, and making the total size 4. In Trec2, B is aligned on a 1-byte boundary, right after A, hence, the total size of the record is 3.
- For Trec3, the sizes of A, B are 1, and hence they are aligned on 1 byte boundaries. The same is true for Trec4.

- For `Trec5`, since the size of `B - 3` is smaller than 4, `B` will be on a 4-byte boundary, as this is the first power of two that is larger than its size. The same holds for `Trec6`.
- For `Trec7`, `B` is aligned on a 4 byte boundary, since its size - 7 - is larger than 4. However, in `Trec8`, it is aligned on a 8-byte boundary, since 8 is the first power of two that is greater than 7, thus making the total size of the record 16.

Free Pascal supports also the 'packed record', this is a record where all the elements are byte-aligned. Thus the two following declarations are equivalent:

```
{ $PackRecords 1 }
Trec2 = Record
  A : Byte;
  B : Word;
end;
{ $PackRecords 2 }
```

and

```
Trec2 = Packed Record
  A : Byte;
  B : Word;
end;
```

Note the `{ $PackRecords 2 }` after the first declaration !

### 3.3.3 Set types

Free Pascal supports the set types as in Turbo Pascal. The prototype of a set declaration is:

#### Set Types

→ set type – **set** – **of** – ordinal type →

Each of the elements of `SetType` must be of type `TargetType`. `TargetType` can be any ordinal type with a range between 0 and 255. A set can contain at most 255 elements. The following are valid set declaration:

```
Type
  Junk = Set of Char;

  Days = (Mon, Tue, Wed, Thu, Fri, Sat, Sun);
  WorkDays : Set of days;
```

Given these declarations, the following assignment is legal:

```
WorkDays := [Mon, Tue, Wed, Thu, Fri];
```

The compiler stores small sets (less than 32 elements) in a `Longint`, if the type range allows it. This allows for faster processing and decreases program size. Otherwise, sets are stored in 32 bytes.

Several operations can be done on sets: taking unions or differences, adding or removing elements, comparisons. These are documented in section [12.8.5](#), page [141](#)

```

    Buffer = String[255];
    BufPtr = ^Buffer;
Var B   : Buffer;
    BP  : BufPtr;
    PP  : Pointer;
etc..

```

In this example, BP *is a pointer to* a Buffer type; while B *is a variable of type* Buffer. B takes 256 bytes memory, and BP only takes 4 (or 8) bytes of memory: enough memory to store an address.

The expression

BP<sup>^</sup>

is known as the dereferencing of BP. The result is of type Buffer, so

BP<sup>^[</sup>23]

Denotes the 23-rd character in the string pointed to by BP.

**Remark:** Free Pascal treats pointers much the same way as C does. This means that a pointer to some type can be treated as being an array of this type.

From this point of view, the pointer then points to the zeroeth element of this array. Thus the following pointer declaration

```
Var p : ^Longint;
```

can be considered equivalent to the following array declaration:

```
Var p : array[0..Infinity] of Longint;
```

The difference is that the former declaration allocates memory for the pointer only (not for the array), and the second declaration allocates memory for the entire array. If the former is used, the memory must be allocated manually, using the Getmem function. The reference P<sup>^</sup> is then the same as p[0]. The following program illustrates this maybe more clear:

```

program PointerArray;
var i : Longint;
    p : ^Longint;
    pp : array[0..100] of Longint;
begin
    for i := 0 to 100 do pp[i] := i; { Fill array }
    p := @pp[0];                    { Let p point to pp }
    for i := 0 to 100 do
        if p[i]<>pp[i] then
            WriteLn ('Ohoh, problem !')
    end.

```

Free Pascal supports pointer arithmetic as C does. This means that, if P is a typed pointer, the instructions

```

Inc(P);
Dec(P);

```

Will increase, respectively decrease the address the pointer points to with the size of the type P is a pointer to. For example

```

Var P : ^Longint;
...
Inc (p);

```

will increase `P` with 4, because 4 is the size of a `longint`. If the pointer is untyped, a size of 1 byte is assumed (i.e. as if the pointer were a pointer to a byte: `^byte`.)

Normal arithmetic operators on pointers can also be used, that is, the following are valid pointer arithmetic operations:

```

var  p1,p2 : ^Longint;
      L : Longint;
begin
  P1 := @P2;
  P2 := @L;
  L := P1-P2;
  P1 := P1-4;
  P2 := P2+4;
end.

```

Here, the value that is added or subtracted *is* multiplied by the size of the type the pointer points to. In the previous example `P1` will be decremented by 16 bytes, and `P2` will be incremented by 16.

### 3.5 Forward type declarations

Programs often need to maintain a linked list of records. Each record then contains a pointer to the next record (and possibly to the previous record as well). For type safety, it is best to define this pointer as a typed pointer, so the next record can be allocated on the heap using the `New` call. In order to do so, the record should be defined something like this:

```

Type
  TListItem = Record
    Data : Integer;
    Next : ^TListItem;
  end;

```

When trying to compile this, the compiler will complain that the `TListItem` type is not yet defined when it encounters the `Next` declaration: This is correct, as the definition is still being parsed.

To be able to have the `Next` element as a typed pointer, a 'Forward type declaration' must be introduced:

```

Type
  PListItem = ^TListItem;
  TListItem = Record
    Data : Integer;
    Next : PListItem;
  end;

```

When the compiler encounters a typed pointer declaration where the referenced type is not yet known, it postpones resolving the reference till later. The pointer definition is a 'Forward type declaration'.

The referenced type should be introduced later in the same `Type` block. No other block may come between the definition of the pointer type and the referenced type. Indeed, even the word `Type`

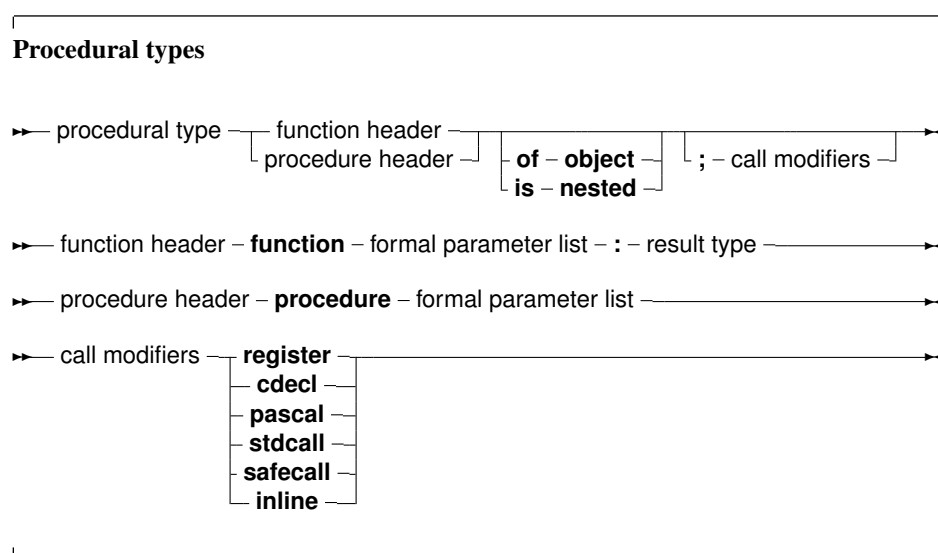

itself may not re-appear: in effect it would start a new type-block, causing the compiler to resolve all pending declarations in the current block.

In most cases, the definition of the referenced type will follow immediately after the definition of the pointer type, as shown in the above listing. The forward defined type can be used in any type definition following its declaration.

Note that a forward type declaration is only possible with pointer types and classes, not with other types.

### 3.6 Procedural types

Free Pascal has support for procedural types, although it differs a little from the Turbo Pascal or Delphi implementation of them. The type declaration remains the same, as can be seen in the following syntax diagram:

For a description of formal parameter lists, see chapter 14, page 165. The two following examples are valid type declarations:

```

Type TOneArg = Procedure (Var X : integer);
    TNoArg = Function : Real;
var proc : TOneArg;
    func : TNoArg;
  
```

One can assign the following values to a procedural type variable:

1. Nil, for both normal procedure pointers and method pointers.
2. A variable reference of a procedural type, i.e. another variable of the same type.
3. A global procedure or function address, with matching function or procedure header and calling convention.
4. A method address.

Given these declarations, the following assignments are valid:

```
Procedure printit (Var X : Integer);
begin
  WriteLn (x);
end;
...
Proc := @printit;
Func := @Pi;
```

From this example, the difference with Turbo Pascal is clear: In Turbo Pascal it isn't necessary to use the address operator (@) when assigning a procedural type variable, whereas in Free Pascal it is required. In case the `-MDelphi` or `-MTP` switches are used, the address operator can be dropped.

**Remark:** The modifiers concerning the calling conventions must be the same as the declaration; i.e. the following code would give an error:

```
Type TOneArgCcall = Procedure (Var X : integer);cdecl;
var proc : TOneArgCcall;
Procedure printit (Var X : Integer);
begin
  WriteLn (x);
end;
begin
Proc := @printit;
end.
```

Because the `TOneArgCcall` type is a procedure that uses the `cdecl` calling convention.

In case the `is nested` modifier is added, then the procedural variable can be used with nested procedures. This requires that the sources be compiled in `macpas` or `ISO` mode, or that the `nestedprocvars` modeswitch be activated:

```
{$modeswitch nestedprocvars}
program tmaclocalproparam3;

type
  tnestedprocvar = procedure is nested;

var
  temp: tnestedprocvar;

procedure p1( pp: tnestedprocvar);
begin
  temp:=pp;
  temp
end;

procedure p2( pp: tnestedprocvar);
var
  localpp: tnestedprocvar;
begin
  localpp:=pp;
  p1( localpp)
end;

procedure n;
```

```
begin
  writeln( 'calling through n')
end;

procedure q;

var qi: longint;

  procedure r;
  begin
    if qi = 1 then
      writeln( 'success for r')
    else
      begin
        writeln( 'fail');
        halt( 1)
      end
    end
  end;

begin
  qi:= 1;
  p1( @r);
  p2( @r);
  p1( @n);
  p2( @n);
end;

begin
  q;
end.
```

In case one wishes to assign methods of a class to a variable of procedural type, the procedural type must be declared with the `of object` modifier.

The two following examples are valid type declarations for method procedural variables (also known as event handlers because of their use in GUI design):

```
Type TOneArg = Procedure (Var X : integer) of object;
     TNoArg = Function : Real of object;
var
  oproc : TOneArg;
  ofunc : TNoArg;
```

A method of the correct signature can be assigned to these functions. When called, `Self` will be pointing to the instance of the object that was used to assign the method procedure.

The following object methods can be assigned to `oproc` and `ofunc`:

```
Type
  TMyObject = Class(TObject)
    Procedure DoX (Var X : integer);
    Function DoY: Real;
  end;

Var
```

```
    M : TMyObject;  
  
begin  
    oproc:=@M.DoX;  
    ofunc:=@M.DOY;  
end;
```

When calling `oproc` and `ofunc`, `Self` will equal `M`.

This mechanism is sometimes called *Delegation*.

## 3.7 Variant types

### 3.7.1 Definition

As of version 1.1, FPC has support for variants. For maximum variant support it is recommended to add the `variants` unit to the `uses` clause of every unit that uses variants in some way: the `variants` unit contains support for examining and transforming variants other than the default support offered by the `System` or `ObjPas` units.

The type of a value stored in a variant is only determined at runtime: it depends what has been assigned to the variant. Almost any simple type can be assigned to variants: ordinal types, string types, `int64` types.

Structured types such as sets, records, arrays, files, objects and classes are not assignment-compatible with a variant, as well as pointers. Interfaces and COM or CORBA objects can be assigned to a variant (basically because they are simply a pointer).

This means that the following assignments are valid:

```
Type  
    TMyEnum = (One,Two,Three);  
  
Var  
    V : Variant;  
    I : Integer;  
    B : Byte;  
    W : Word;  
    Q : Int64;  
    E : Extended;  
    D : Double;  
    En : TMyEnum;  
    AS : AnsiString;  
    WS : WideString;  
  
begin  
    V:=I;  
    V:=B;  
    V:=W;  
    V:=Q;  
    V:=E;  
    V:=En;  
    V:=D;  
    V:=AS;  
    V:=WS;  
end;
```

And of course vice-versa as well.

A variant can hold an array of values: All elements in the array have the same type (but can be of type 'variant'). For a variant that contains an array, the variant can be indexed:

```
Program testv;  
  
uses variants;  
  
Var  
  A : Variant;  
  I : integer;  
  
begin  
  A:=VarArrayCreate([1,10],varInteger);  
  For I:=1 to 10 do  
    A[I]:=I;  
  end.
```

For the explanation of `VarArrayCreate`, see [Unit Reference](#).

Note that when the array contains a string, this is not considered an 'array of characters', and so the variant cannot be indexed to retrieve a character at a certain position in the string.

### 3.7.2 Variants in assignments and expressions

As can be seen from the definition above, most simple types can be assigned to a variant. Likewise, a variant can be assigned to a simple type: If possible, the value of the variant will be converted to the type that is being assigned to. This may fail: Assigning a variant containing a string to an integer will fail unless the string represents a valid integer. In the following example, the first assignment will work, the second will fail:

```
program testv3;  
  
uses Variants;  
  
Var  
  V : Variant;  
  I : Integer;  
  
begin  
  V:='100';  
  I:=V;  
  Writeln('I : ',I);  
  V:='Something else';  
  I:=V;  
  Writeln('I : ',I);  
end.
```

The first assignment will work, but the second will not, as `Something else` cannot be converted to a valid integer value. An `EConvertError` exception will be the result.

The result of an expression involving a variant will be of type variant again, but this can be assigned to a variable of a different type - if the result can be converted to a variable of this type.

Note that expressions involving variants take more time to be evaluated, and should therefore be used with caution. If a lot of calculations need to be made, it is best to avoid the use of variants.

When considering implicit type conversions (e.g. byte to integer, integer to double, char to string) the compiler will ignore variants unless a variant appears explicitly in the expression.

### 3.7.3 Variants and interfaces

**Remark:** Dispatch interface support for variants is currently broken in the compiler.

Variants can contain a reference to an interface - a normal interface (descending from `IInterface`) or a dispatchinterface (descending from `IDispatch`). Variants containing a reference to a dispatch interface can be used to control the object behind it: the compiler will use late binding to perform the call to the dispatch interface: there will be no run-time checking of the function names and parameters or arguments given to the functions. The result type is also not checked. The compiler will simply insert code to make the dispatch call and retrieve the result.

This means basically, that you can do the following on Windows:

```
Var
  W : Variant;
  V : String;

begin
  W:=CreateOleObject('Word.Application');
  V:=W.Application.Version;
  Writeln('Installed version of MS Word is : ',V);
end;
```

The line

```
V:=W.Application.Version;
```

is executed by inserting the necessary code to query the dispatch interface stored in the variant `W`, and execute the call if the needed dispatch information is found.

## 3.8 Type aliases

Type aliases are a way to give another name to a type, but can also be used to create real new types. Which of the 2 depends on the way the type alias is defined:

The first case is just a means to give another name to a type:

```
Type
  MyInteger = Integer;
```

This creates a new name to refer to the `Integer` type, but does not create an actual new type. That is, 2 variables:

```
Var
  A : MyInteger;
  B : Integer;
```

Will actually have the same type from the point of view of the compiler (namely: `Integer`).

The above presents a way to make types platform independent, by only using the alias types, and then defining these types for each platform individually. Any programmer who then uses these custom types doesn't have to worry about the underlying type size: it is opaque to him. It also allows to use shortcut names for fully qualified type names. e.g. define `system.longint` as `Olongint` and then redefine `longint`.

The alias is frequently seen to re-expose a type:

```
Unit A;

Interface

Uses B;

Type
  MyType = B.MyType;
```

This construction is often seen after some refactoring, when moving some declarations from unit A to unit B, to preserve backwards compatibility of the interface of unit A.

The second case is slightly more subtle:

```
Type
  MyInteger = Type Integer;
```

This not only creates a new name to refer to the `Integer` type, but actually creates a new type. That is, 2 variables:

```
Var
  A : MyInteger;
  B : Integer;
```

Will not have the same type from the point of view of the compiler. However, these 2 types will be assignment compatible. That means that an assignment

```
A:=B;
```

will work.

The difference can be seen when examining type information:

```
If TypeInfo(MyInteger) <> TypeInfo(Integer) then
  Writeln('MyInteger and Integer are different types');
```

The compiler function `TypeInfo` returns a pointer to the type information in the binary. Since the 2 types `MyInteger` and `Integer` are different, they will generate different type information blocks, and the pointers will differ.

There are 3 consequences of having different types:

1. That they have different typeinfo, hence different RTTI (Run-Time Type Information).

2. They can be used in function overloads, that is

```
Procedure MyProc(A : MyInteger); overload;  
Procedure MyProc(A : Integer); overload;
```

will work. This will not work with a simple type alias.

3. They can be used in operator overloads, that is

```
Operator +(A,B : MyInteger) : MyInteger;
```

will work too.

## Chapter 4

# Variables

### 4.1 Definition

Variables are explicitly named memory locations with a certain type. When assigning values to variables, the Free Pascal compiler generates machine code to move the value to the memory location reserved for this variable. Where this variable is stored depends on where it is declared:

- Global variables are variables declared in a unit or program, but not inside a procedure or function. They are stored in fixed memory locations, and are available during the whole execution time of the program.
- Local variables are declared inside a procedure or function. Their value is stored on the program stack, i.e. not at fixed locations.

The Free Pascal compiler handles the allocation of these memory locations transparently, although this location can be influenced in the declaration.

The Free Pascal compiler also handles reading values from or writing values to the variables transparently. But even this can be explicitly handled by the programmer when using properties.

Variables must be explicitly declared when they are needed. No memory is allocated unless a variable is declared. Using a variable identifier (for instance, a loop variable) which is not declared first, is an error which will be reported by the compiler.

### 4.2 Declaration

The variables must be declared in a variable declaration block of a unit or a procedure or function (section 16.4, page 198). It looks as follows:

This means that the following are valid variable declarations:

Var

```

curterm1 : integer;

curterm2 : integer; cvar;
curterm3 : integer; cvar; external;

curterm4 : integer; external name 'curterm3';
curterm5 : integer; external 'libc' name 'curterm9';

curterm6 : integer absolute curterm1;

curterm7 : integer; cvar; export;
curterm8 : integer; cvar; public;
curterm9 : integer; export name 'me';
curterm10 : integer; public name 'ma';

curterm11 : integer = 1 ;

```

The difference between these declarations is as follows:

1. The first form (`curterm1`) defines a regular variable. The compiler manages everything by itself.
2. The second form (`curterm2`) declares also a regular variable, but specifies that the assembler name for this variable equals the name of the variable as written in the source.
3. The third form (`curterm3`) declares a variable which is located externally: the compiler will assume memory is located elsewhere, and that the assembler name of this location is specified by the name of the variable, as written in the source. The name may not be specified.
4. The fourth form is completely equivalent to the third, it declares a variable which is stored externally, and explicitly gives the assembler name of the location. If `cvar` is not used, the name must be specified.
5. The fifth form is a variant of the fourth form, only the name of the library in which the memory is reserved is specified as well.
6. The sixth form declares a variable (`curterm6`), and tells the compiler that it is stored in the same location as another variable (`curterm1`).
7. The seventh form declares a variable (`curterm7`), and tells the compiler that the assembler label of this variable should be the name of the variable (case sensitive) and must be made public. i.e. it can be referenced from other object files.

8. The eighth form (`curterm8`) is equivalent to the seventh: `'public'` is an alias for `'export'`.
9. The ninth and tenth form are equivalent: they specify the assembler name of the variable.
10. the eleventh form declares a variable (`curterm11`) and initializes it with a value (1 in the above case).

Note that assembler names must be unique. It's not possible to declare or export 2 variables with the same assembler name.

## 4.3 Scope

Variables, just as any identifier, obey the general rules of scope. In addition, initialized variables are initialized when they enter scope:

- Global initialized variables are initialized once, when the program starts.
- Local initialized variables are initialized each time the procedure is entered.

Note that the behaviour for local initialized variables is different from the one of a local typed constant. A local typed constant behaves like a global initialized variable.

## 4.4 Initialized variables

By default, variables in Pascal are not initialized after their declaration. Any assumption that they contain 0 or any other default value is erroneous: They can contain rubbish. To remedy this, the concept of initialized variables exists. The difference with normal variables is that their declaration includes an initial value, as can be seen in the diagram in the previous section.

Given the declaration:

```
Var
  S : String = 'This is an initialized string';
```

The value of the variable following will be initialized with the provided value. The following is an even better way of doing this:

```
Const
  SDefault = 'This is an initialized string';

Var
  S : String = SDefault;
```

Initialization is often used to initialize arrays and records. For arrays, the initialized elements must be specified, surrounded by round brackets, and separated by commas. The number of initialized elements must be exactly the same as the number of elements in the declaration of the type. As an example:

```
Var
  tt : array [1..3] of string[20] = ('ikke', 'gij', 'hij');
  ti : array [1..3] of Longint = (1,2,3);
```

For constant records, each element of the record should be specified, in the form `Field: Value`, separated by semicolons, and surrounded by round brackets. As an example:

```

Type
  Point = record
    X, Y : Real
  end;
Var
  Origin : Point = (X:0.0; Y:0.0);

```

The order of the fields in a constant record needs to be the same as in the type declaration, otherwise a compile-time error will occur.

**Remark:** It should be stressed that initialized variables are initialized when they come into scope, in difference with typed constants, which are initialized at program start. This is also true for *local* initialized variables. Local initialized are initialized whenever the routine is called. Any changes that occurred in the previous invocation of the routine will be undone, because they are again initialized.

## 4.5 Thread Variables

For a program which uses threads, the variables can be really global, i.e. the same for all threads, or thread-local: this means that each thread gets a copy of the variable. Local variables (defined inside a procedure) are always thread-local. Global variables are normally the same for all threads. A global variable can be declared thread-local by replacing the `var` keyword at the start of the variable declaration block with `Threadvar`:

```

Threadvar
  IOResult : Integer;

```

If no threads are used, the variable behaves as an ordinary variable. If threads are used then a copy is made for each thread (including the main thread). Note that the copy is made with the original value of the variable, *not* with the value of the variable at the time the thread is started.

Threadvars should be used sparingly: There is an overhead for retrieving or setting the variable's value. If possible at all, consider using local variables; they are always faster than thread variables.

Threads are not enabled by default. For more information about programming threads, see the chapter on threads in the [Programmer's Guide](#).

## 4.6 Properties

A global block can declare properties, just as they could be defined in a class. The difference is that the global property does not need a class instance: there is only 1 instance of this property. Other than that, a global property behaves like a class property. The read/write specifiers for the global property must also be regular procedures, not methods.

The concept of a global property is specific to Free Pascal, and does not exist in Delphi. `ObjFPC` mode is required to work with properties.

The concept of a global property can be used to 'hide' the location of the value, or to calculate the value on the fly, or to check the values which are written to the property.

The declaration is as follows:

The following is an example:

```

{$mode objfpc}
unit testprop;

Interface

Function GetMyInt : Integer;
Procedure SetMyInt(Value : Integer);

Property
  MyProp : Integer Read GetMyInt Write SetMyInt;

Implementation

Uses sysutils;

Var
  FMyInt : Integer;

Function GetMyInt : Integer;

begin
  Result:=FMyInt;
end;

Procedure SetMyInt(Value : Integer);

begin
  
```

```
    If ((Value mod 2)=1) then
        Raise Exception.Create('MyProp can only contain even value');
    FMyInt:=Value;
end;

end.
```

The read/write specifiers can be hidden by declaring them in another unit which must be in the `uses` clause of the unit. This can be used to hide the read/write access specifiers for programmers, just as if they were in a `private` section of a class (discussed below). For the previous example, this could look as follows:

```
{ $mode objfpc }
unit testrw;

Interface

Function GetMyInt : Integer;
Procedure SetMyInt (Value : Integer);

Implementation

Uses sysutils;

Var
    FMyInt : Integer;

Function GetMyInt : Integer;

begin
    Result:=FMyInt;
end;

Procedure SetMyInt (Value : Integer);

begin
    If ((Value mod 2)=1) then
        Raise Exception.Create('Only even values are allowed');
    FMyInt:=Value;
end;

end.
```

The unit `testprop` would then look like:

```
{ $mode objfpc }
unit testprop;

Interface

uses testrw;

Property
    MyProp : Integer Read GetMyInt Write SetMyInt;
```

Implementation

end.

More information about properties can be found in chapter [6](#), page [72](#).

## Chapter 5

# Objects

### 5.1 Declaration

Free Pascal supports object oriented programming. In fact, most of the compiler is written using objects. Here we present some technical questions regarding object oriented programming in Free Pascal.

Objects should be treated as a special kind of record. The record contains all the fields that are declared in the objects definition, and pointers to the methods that are associated to the objects' type.

An object is declared just as a record would be declared; except that now, procedures and functions can be declared as if they were part of the record. Objects can "inherit" fields and methods from "parent" objects. This means that these fields and methods can be used as if they were included in the objects declared as a "child" object.

Furthermore, a concept of visibility is introduced: fields, procedures and functions can be declared as `public`, `protected` or `private`. By default, fields and methods are `public`, and are exported outside the current unit.

Fields or methods that are declared `private` are only accessible in the current unit: their scope is limited to the implementation of the current unit.

The prototype declaration of an object is as follows:

As can be seen, as many `private` and `public` blocks as needed can be declared.

The following is a valid definition of an object:

```
Type
  TObj = object
  Private
    Caption : ShortString;
  Public
    Constructor init;
    Destructor done;
    Procedure SetCaption (AValue : String);
    Function GetCaption : String;
end;
```

It contains a constructor/destructor pair, and a method to get and set a caption. The `Caption` field is private to the object: it cannot be accessed outside the unit in which `TObj` is declared.

**Remark:** In MacPas mode, the `Object` keyword is replaced by the `class` keyword for compatibility with other pascal compilers available on the Mac. That means that objects cannot be used in MacPas mode.

**Remark:** Free Pascal also supports the packed object. This is the same as an object, only the elements (fields) of the object are byte-aligned, just as in the packed record. The declaration of a packed object is similar to the declaration of a packed record :

```
Type
  TObj = packed object
    Constructor init;
    ...
  end;
  Pobj = ^TObj;
Var PP : Pobj;
```

Similarly, the `{ $PackRecords }` directive acts on objects as well.

## 5.2 Fields

Object Fields are like record fields. They are accessed in the same way as a record field would be accessed : by using a qualified identifier. Given the following declaration:

```
Type TAnObject = Object
  AField : Longint;
  Procedure AMethod;
  end;
Var AnObject : TAnObject;
```

then the following would be a valid assignment:

```
AnObject.AField := 0;
```

Inside methods, fields can be accessed using the short identifier:

```
Procedure TAnObject.AMethod;
begin
  ...
  AField := 0;
  ...
end;
```

Or, one can use the `self` identifier. The `self` identifier refers to the current instance of the object:

```
Procedure TAnObject.AMethod;
begin
  ...
  Self.AField := 0;
  ...
end;
```

One cannot access fields that are in a private or protected sections of an object from outside the objects' methods. If this is attempted anyway, the compiler will complain about an unknown identifier.

It is also possible to use the `with` statement with an object instance, just as with a record:

```
With AnObject do
begin
  Afield := 12;
  AMethod;
end;
```

In this example, between the `begin` and `end`, it is as if `AnObject` was prepended to the `Afield` and `AMethod` identifiers. More about this in [section 13.2.8](#), page 162.

## 5.3 Static fields

When the `{$STATIC ON}` directive is active, then an object can contain static fields: these fields are global to the object type, and act like global variables, but are known only as part of the object. They can be referenced from within the objects methods, but can also be referenced from outside the object by providing the fully qualified name.

For instance, the output of the following program:

```
{$static on}
type
  cl=object
    l : longint;static;
  end;
var
  cl1,cl2 : cl;
begin
  cl1.l:=2;
  writeln(cl2.l);
  cl2.l:=3;
  writeln(cl1.l);
  Writeln(cl.l);
end.
```

will be the following

```
2
3
3
```

Note that the last line of code references the object type itself (`c1`), and not an instance of the object (`c11` or `c12`).

## 5.4 Constructors and destructors

As can be seen in the syntax diagram for an object declaration, Free Pascal supports constructors and destructors. The programmer is responsible for calling the constructor and the destructor explicitly when using objects.

The declaration of a constructor or destructor is as follows:

A constructor/destructor pair is *required* if the object uses virtual methods. The reason is that for an object with virtual methods, some internal housekeeping must be done: this housekeeping is done by the constructor<sup>1</sup>.

In the declaration of the object type, a simple identifier should be used for the name of the constructor or destructor. When the constructor or destructor is implemented, a qualified method identifier should be used, i.e. an identifier of the form `objectidentifier.methodidentifier`.

Free Pascal supports also the extended syntax of the `New` and `Dispose` procedures. In case a dynamic variable of an object type must be allocated the constructor's name can be specified in the call to `New`. The `New` is implemented as a function which returns a pointer to the instantiated object. Consider the following declarations:

```
Type
  TObj = object;
    Constructor init;
    ...
  end;
  PObj = ^TObj;
Var PP : PObj;
```

<sup>1</sup>A pointer to the VMT must be set up.

Then the following 3 calls are equivalent:

```
pp := new (Pobj, Init);
```

and

```
new(pp, init);
```

and also

```
new (pp);  
pp^.init;
```

In the last case, the compiler will issue a warning that the extended syntax of `new` and `dispose` must be used to generate instances of an object. It is possible to ignore this warning, but it's better programming practice to use the extended syntax to create instances of an object. Similarly, the `Dispose` procedure accepts the name of a destructor. The destructor will then be called, before removing the object from the heap.

In view of the compiler warning remark, the following chapter presents the Delphi approach to object-oriented programming, and may be considered a more natural way of object-oriented programming.

## 5.5 Methods

Object methods are just like ordinary procedures or functions, only they have an implicit extra parameter: `self`. `Self` points to the object with which the method was invoked. When implementing methods, the fully qualified identifier must be given in the function header. When declaring methods, a normal identifier must be given.

### 5.5.1 Declaration

The declaration of a method is much like a normal function or procedure declaration, with some additional specifiers, as can be seen from the following diagram, which is part of the object declaration:

from the point of view of declarations, `Method definitions` are normal function or procedure declarations. Contrary to TP and Delphi, fields can be declared after methods in the same block, i.e. the following will generate an error when compiling with Delphi or Turbo Pascal, but not with FPC:

Type

```
MyObj = Object
  Procedure Doit;
  Field : Longint;
end;
```

### 5.5.2 Method invocation

Methods are called just as normal procedures are called, only they have an object instance identifier prepended to them (see also chapter 13, page 146). To determine which method is called, it is necessary to know the type of the method. We treat the different types in what follows.

#### Static methods

Static methods are methods that have been declared without a `abstract` or `virtual` keyword. When calling a static method, the declared (i.e. compile time) method of the object is used. For example, consider the following declarations:

Type

```
TParent = Object
  ...
  procedure Doit;
  ...
end;
PParent = ^TParent;
TChild = Object (TParent)
  ...
  procedure Doit;
  ...
end;
PChild = ^TChild;
```

As it is visible, both the parent and child objects have a method called `Doit`. Consider now the following declarations and calls:

Var

```
ParentA, ParentB : PParent;
Child             : PChild;
```

begin

```
  ParentA := New(PParent, Init);
  ParentB := New(PChild, Init);
  Child := New(PChild, Init);
  ParentA^.Doit;
  ParentB^.Doit;
  Child^.Doit;
```

Of the three invocations of `Doit`, only the last one will call `TChild.Doit`, the other two calls will call `TParent.Doit`. This is because for static methods, the compiler determines at compile time which method should be called. Since `ParentB` is of type `TParent`, the compiler decides that it must be called with `TParent.Doit`, even though it will be created as a `TChild`. There may be times when the method that is actually called should depend on the actual type of the object at run-time. If so, the method cannot be a static method, but must be a virtual method.

## Virtual methods

To remedy the situation in the previous section, virtual methods are created. This is simply done by appending the method declaration with the `virtual` modifier. The descendent object can then override the method with a new implementation by re-declaring the method (with the same parameter list) using the `virtual` keyword.

Going back to the previous example, consider the following alternative declaration:

```
Type
  TParent = Object
  ...
  procedure Doit;virtual;
  ...
end;
PParent = ^TParent;
TChild = Object(TParent)
  ...
  procedure Doit;virtual;
  ...
end;
PChild = ^TChild;
```

As it is visible, both the parent and child objects have a method called `Doit`. Consider now the following declarations and calls :

```
Var
  ParentA, ParentB : PParent;
  Child           : PChild;

begin
  ParentA := New(PParent, Init);
  ParentB := New(PChild, Init);
  Child := New(PChild, Init);
  ParentA^.Doit;
  ParentB^.Doit;
  Child^.Doit;
```

Now, different methods will be called, depending on the actual run-time type of the object. For `ParentA`, nothing changes, since it is created as a `TParent` instance. For `Child`, the situation also doesn't change: it is again created as an instance of `TChild`.

For `ParentB` however, the situation does change: Even though it was declared as a `TParent`, it is created as an instance of `TChild`. Now, when the program runs, before calling `Doit`, the program checks what the actual type of `ParentB` is, and only then decides which method must be called. Seeing that `ParentB` is of type `TChild`, `TChild.Doit` will be called. The code for this run-time checking of the actual type of an object is inserted by the compiler at compile time.

The `TChild.Doit` is said to *override* the `TParent.Doit`. It is possible to access the `TParent.Doit` from within the `varTChild.Doit`, with the `inherited` keyword:

```
Procedure TChild.Doit;
begin
  inherited Doit;
  ...
end;
```

In the above example, when `TChild.Doit` is called, the first thing it does is call `TParent.Doit`. The inherited keyword cannot be used in static methods, only on virtual methods.

To be able to do this, the compiler keeps - per object type - a table with virtual methods: the VMT (Virtual Method Table). This is simply a table with pointers to each of the virtual methods: each virtual method has its fixed location in this table (an index). The compiler uses this table to look up the actual method that must be used. When a descendent object overrides a method, the entry of the parent method is overwritten in the VMT. More information about the VMT can be found in [Programmer's Guide](#).

As remarked earlier, objects that have a VMT must be initialized with a constructor: the object variable must be initialized with a pointer to the VMT of the actual type that it was created with.

### Abstract methods

An abstract method is a special kind of virtual method. A method that is declared `abstract` does not have an implementation for this method. It is up to inherited objects to override and implement this method.

From this it follows that a method can not be abstract if it is not virtual (this can be seen from the syntax diagram). A second consequence is that an instance of an object that has an abstract method cannot be created directly.

The reason is obvious: there is no method where the compiler could jump to ! A method that is declared `abstract` does not have an implementation for this method. It is up to inherited objects to override and implement this method. Continuing our example, take a look at this:

```
Type
  TParent = Object
    ...
    procedure Doit;virtual;abstract;
    ...
  end;
  PParent=^TParent;
  TChild = Object(TParent)
    ...
    procedure Doit;virtual;
    ...
  end;
  PChild = ^TChild;
```

As it is visible, both the parent and child objects have a method called `Doit`. Consider now the following declarations and calls :

```
Var
  ParentA,ParentB : PParent;
  Child           : PChild;

begin
  ParentA := New(PParent, Init);
  ParentB := New(PChild, Init);
  Child := New(PChild, Init);
  ParentA^.Doit;
  ParentB^.Doit;
  Child^.Doit;
```

First of all, Line 3 will generate a compiler error, stating that one cannot generate instances of objects with abstract methods: The compiler has detected that `PParent` points to an object which has an abstract method. Commenting line 3 would allow compilation of the program.

**Remark:** If an abstract method is overridden, the parent method cannot be called with `inherited`, since there is no parent method; The compiler will detect this, and complain about it, like this:

```
testo.pp(32,3) Error: Abstract methods can't be called directly
```

If, through some mechanism, an abstract method is called at run-time, then a run-time error will occur. (run-time error 211, to be precise)

## 5.6 Visibility

For objects, 3 visibility specifiers exist : `private`, `protected` and `public`. If a visibility specifier is not specified, `public` is assumed. Both methods and fields can be hidden from a programmer by putting them in a `private` section. The exact visibility rule is as follows:

**Private** All fields and methods that are in a `private` block, can only be accessed in the module (i.e. unit or program) that contains the object definition. They can be accessed from inside the object's methods or from outside them e.g. from other objects' methods, or global functions.

**Protected** Is the same as `Private`, except that the members of a `Protected` section are also accessible to descendent types, even if they are implemented in other modules.

**Public** fields and methods are always accessible, from everywhere. Fields and methods in a `public` section behave as though they were part of an ordinary `record` type.

# Chapter 6

## Classes

In the Delphi approach to Object Oriented Programming, everything revolves around the concept of 'Classes'. A class can be seen as a pointer to an object, or a pointer to a record, with methods associated with it.

The difference between objects and classes is mainly that an object is allocated on the stack, as an ordinary record would be, and that classes are always allocated on the heap. In the following example:

```
Var
  A : TSomeObject; // an Object
  B : TSomeClass;  // a Class
```

The main difference is that the variable A will take up as much space on the stack as the size of the object (TSomeObject). The variable B, on the other hand, will always take just the size of a pointer on the stack. The actual class data is on the heap.

From this, a second difference follows: a class must *always* be initialized through its constructor, whereas for an object, this is not necessary. Calling the constructor allocates the necessary memory on the heap for the class instance data.

**Remark:** In earlier versions of Free Pascal it was necessary, in order to use classes, to put the `objpas` unit in the uses clause of a unit or program. *This is no longer needed* as of version 0.99.12. As of this version, the unit will be loaded automatically when the `-MObjfpc` or `-MDelphi` options are specified, or their corresponding directives are used:

```
{ $mode objfpc }
{ $mode delphi }
```

In fact, the compiler will give a warning if it encounters the `objpas` unit in a uses clause.

### 6.1 Class definitions

The prototype declaration of a class is as follows:

**Remark:** In MacPas mode, the `Object` keyword is replaced by the `class` keyword for compatibility with other pascal compilers available on the Mac. That means that in MacPas mode, the reserved word 'class' in the above diagram may be replaced by the reserved word 'object'.

In a class declaration, as many `private`, `protected`, `published` and `public` blocks as needed can be used: the various blocks can be repeated, and there is no special order in which they must appear.

Methods are normal function or procedure declarations. As can be seen, the declaration of a class is almost identical to the declaration of an object. The real difference between objects and classes is in the way they are created (see further in this chapter).

The visibility of the different sections is as follows:

**Private** All fields and methods that are in a `private` block, can only be accessed in the module (i.e. unit) that contains the class definition. They can be accessed from inside the classes' methods or from outside them (e.g. from other classes' methods)

**Strict Private** All fields and methods that are in a `strict private` block, can only be accessed from methods of the class itself. Other classes or descendent classes (even in the same unit) cannot access strict private members.

**Protected** Is the same as `Private`, except that the members of a `Protected` section are also accessible to descendent types, even if they are implemented in other modules.

**Strict Protected** Is the same as `Protected`, except that the members of a `Protected` section are also accessible to other classes implemented in the same unit. `Strict protected` members are only visible to descendent classes, not to other classes in the same unit.

**Public** sections are always accessible.

**Published** Is the same as a `Public` section, but the compiler generates also type information that is needed for automatic streaming of these classes if the compiler is in the `{ $M+ }` state. Fields defined in a `published` section must be of class type. Array properties cannot be in a `published` section.

In the syntax diagram, it can be seen that a class can list implemented interfaces. This feature will be discussed in the next chapter.

Classes can contain `Class` methods: these are functions that do not require an instance. The `Self` identifier is valid in such methods, but refers to the class pointer (the VMT).

Similar to objects, if the `{ $STATIC ON }` directive is active, then a class can contain static fields: these fields are global to the class, and act like global variables, but are known only as part of the class. They can be referenced from within the classes' methods, but can also be referenced from outside the class by providing the fully qualified name.

For instance, the output of the following program:

```
{ $mode objfpc }
{ $static on }
type
  cl=class
    l : longint; static;
  end;
var
  cl1, cl2 : cl;
begin
  cl1:=cl.create;
  cl2:=cl.create;
  cl1.l:=2;
  writeln(cl2.l);
  cl2.l:=3;
  writeln(cl1.l);
  Writeln(cl.l);
end.
```

will be the following

```
2
3
3
```

Note that the last line of code references the class type itself (`c1`), and not an instance of the class (`c11` or `c12`).

**Remark:** Like with functions and pointer types, sometimes a forward definition of a class is needed. A class forward definition is simply the name of the class, with the keyword `Class`, as in the following example:

```
Type
  TClassB = Class;
  TClassA = Class
    B : TClassB;
  end;

  TClassB = Class
    A : TClassA;
  end;
```

When using a class forward definition, the class must be defined in the same unit, in the same section (interface/implementation). It must not necessarily be defined in the same type section.

It is also possible to define class reference types:

Class reference types are used to create instances of a certain class, which is not yet known at compile time, but which is specified at run time. Essentially, a variable of a class reference type contains a pointer to the definition of the specified class. This can be used to construct an instance of the class corresponding to the definition, or to check inheritance. The following example shows how it works:

```
Type
  TComponentClass = Class of TComponent;

Function CreateComponent (AClass: TComponentClass;
                        AOwner: TComponent): TComponent;

begin
  // ...
  Result:=AClass.Create (AOwner);
  // ...
end;
```

This function can be passed a class reference of any class that descends from `TComponent`. The following is a valid call:

```
Var
  C : TComponent;

begin
  C:=CreateComponent (TEdit, Form1);
end;
```

On return of the `CreateComponent` function, `C` will contain an instance of the class `TEdit`. Note that the following call will fail to compile:

```
Var
  C : TComponent;

begin
  C:=CreateComponent (TStream, Form1);
end;
```

because `TStream` does not descend from `TComponent`, and `AClass` refers to a `TComponent` class. The compiler can (and will) check this at compile time, and will produce an error.

References to classes can also be used to check inheritance:

```
TMinClass = Class of TMyClass;
TMaxClass = Class of TMyClassChild;

Function CheckObjectBetween (Instance : TObject) : boolean;

begin
  If not (Instance is TMinClass)
    or ((Instance is TMaxClass)
        and (Instance.ClassType<>TMaxClass)) then
    Raise Exception.Create (SomeError)
end;
```

The above example will raise an exception if the passed instance is not a descendent of `TMinClass` or a descendent of `TMaxClass`.

More about instantiating a class can be found in the next section.

## 6.2 Class instantiation

Classes must be created using one of their constructors (there can be multiple constructors). Remember that a class is a pointer to an object on the heap. When a variable of some class is declared, the compiler just allocates room for this pointer, not the entire object. The constructor of a class returns a pointer to an initialized instance of the object on the heap. So, to initialize an instance of some class, one would do the following :

```
ClassVar := ClassType.ConstructorName;
```

The extended syntax of `new` and `dispose` can *not* be used to instantiate and destroy class instances. That construct is reserved for use with objects only. Calling the constructor will provoke a call to `getmem`, to allocate enough space to hold the class instance data. After that, the constructor's code is executed. The constructor has a pointer to its data, in `Self`.

**Remark:**

- The `{ $PackRecords }` directive also affects classes, i.e. the alignment in memory of the different fields depends on the value of the `{ $PackRecords }` directive.
- Just as for objects and records, a packed class can be declared. This has the same effect as on an object, or record, namely that the elements are aligned on 1-byte boundaries, i.e. as close as possible.
- `SizeOf(class)` will return the same as `SizeOf(Pointer)`, since a class is a pointer to an object. To get the size of the class instance data, use the `TObject.InstanceSize` method.

### 6.3 Class destruction

Class instances must be destroyed using the destructor. In difference with the constructor, there is no choice in destructors: the destructor *must* have the name `Destroy`, it *must* override the `Destroy` destructor declared in `TObject`, cannot have arguments, and the inherited destructor must always be called.

To avoid calling a destructor on a `Nil` instance, it is best to call the `Free` method of `TObject`. This method will check if `Self` is not `Nil`, and if so, then it calls `Destroy`. If `Self` equals `Nil`, it will just exit.

Destroying an instance does not free a reference to an instance:

```
Var
  A : TComponent;

begin
  A:=TComponent.Create;
  A.Name:='MyComponent';
  A.Free;
  Writeln('A is still assigned: ',Assigned(A));
end.
```

After the call to `Free`, the variable `A` will not be `Nil`, the output of this program will be:

```
A is still assigned: TRUE
```

To make sure that the variable `A` is cleared after the destructor was called, the function `FreeAndNil` from the `SysUtils` unit can be used. It will call `Free` and will then write `Nil` in the object pointer (`A` in the above example):

```
Var
  A : TComponent;

begin
  A:=TComponent.Create;
  A.Name:='MyComponent';
  FreeAndNil(A);
  Writeln('A is still assigned: ',Assigned(A));
end.
```

After the call to `FreeAndNil`, the variable `A` will contain `Nil`, the output of this program will be:

```
A is still assigned: FALSE
```

Warning: An inherited method is hidden by OBJCHILD.MYPROC

The compiler will compile it, but using `Inherited` can produce strange effects.

The correct declaration is as follows:

```
Type
  ObjParent = Class
    Procedure MyProc; virtual;
  end;
  ObjChild  = Class(ObjParent)
    Procedure MyProc; override;
  end;
```

This will compile and run without warnings or errors.

If the virtual method should really be replaced with a method with the same name, then the `reintroduce` keyword can be used:

```
Type
  ObjParent = Class
    Procedure MyProc; virtual;
  end;
  ObjChild  = Class(ObjParent)
    Procedure MyProc; reintroduce;
  end;
```

This new method is no longer virtual.

To be able to do this, the compiler keeps - per class type - a table with virtual methods: the VMT (Virtual Method Table). This is simply a table with pointers to each of the virtual methods: each virtual method has its fixed location in this table (an index). The compiler uses this table to look up the actual method that must be used at runtime. When a descendent object overrides a method, the entry of the parent method is overwritten in the VMT. More information about the VMT can be found in [Programmer's Guide](#).

**Remark:** The keyword 'virtual' can be replaced with the 'dynamic' keyword: dynamic methods behave the same as virtual methods. Unlike in Delphi, in FPC the implementation of dynamic methods is equal to the implementation of virtual methods.

#### 6.4.4 Class methods

Class methods are identified by the keyword `Class` in front of the procedure or function declaration, as in the following example:

```
Class Function ClassName : String;
```

Class methods are methods that do not have an instance (i.e. `Self` does not point to a class instance) but which follow the scoping and inheritance rules of a class. They can be used to return information about the current class, for instance for registration or use in a class factory. Since no instance is available, no information available in instances can be used.

Class methods can be called from inside a regular method, but can also be called using a class identifier:

```
Var
  AClass : TClass; // AClass is of type "type of class"
```

```
begin
  ..
  if CompareText (AClass.ClassName, 'TCOMPONENT')=0 then
  ...
```

But calling them from an instance is also possible:

```
Var
  MyClass : TObject;

begin
  ..
  if MyClass.ClassNameis ('TCOMPONENT') then
  ...
```

The reverse is not possible: Inside a class method, the `Self` identifier points to the VMT table of the class. No fields, properties or regular methods are available inside a class method. Accessing a regular property or method will result in a compiler error.

Note that class methods can be virtual, and can be overridden.

Class methods can be used as read or write specifiers for a regular property, but naturally, this property will have the same value for all instances of the class, since there is no instance available in the class method.

### 6.4.5 Class constructors and destructors

A class constructor or destructor can also be created. They serve to instantiate some class variables or class properties which must be initialized before a class can be used. These constructors are called automatically at program startup: The constructor is called before the initialization section of the unit it is declared in, the destructor is called after the finalisation section of the unit it is declared in.

There are some caveats when using class destructors/constructors:

- The constructor must be called `Create` and can have no parameters.
- The destructor must be called `Destroy` and can have no parameters.
- Neither constructor nor destructor can be virtual.
- The class constructor/destructor is called irrespective of the use of the class: even if a class is never used, the constructor and destructor are called anyway.

The following program:

```
{ $mode objfpc }
{ $h+ }

Type
  TA = Class (TObject)
  Private
    Function GetA : Integer;
    Procedure SetA (AValue : integer);
```

```
public
  Class Constructor create;
  Class Destructor destroy;
  Property A : Integer Read GetA Write SetA;
end;

{Class} Function TA.GetA : Integer;

begin
  Result:=-1;
end;

{Class} Procedure TA.SetA(AValue : integer);

begin
  //
end;

Class Constructor TA.Create;

begin
  Writeln('Class constructor TA');
end;

Class Destructor TA.Destroy;

begin
  Writeln('Class destructor TA');

end;

Var
  A : TA;

begin
end.
```

Will, when run, output the following:

```
Class constructor TA
Class destructor TA
```

### 6.4.6 Static class methods

FPC knows static class methods in classes: these are class methods that have the `Static` keyword at the end. These methods behave completely like regular procedures or functions. This means that:

- They do not have a `Self` parameter. As a result, they cannot access properties or fields or regular methods.
- They cannot be virtual.
- They can be assigned to regular procedural variables.

Their use is mainly to include the method in the namespace of the class as opposed to having the procedure in the namespace of the unit. Note that they do have access to all class variables, types etc, meaning something like this is possible:

```
{ $mode objfpc }
{ $h+ }

Type
  TA = Class(TObject)
  Private
    class var myprivateA : integer;
  public
    class Function GetA : Integer; static;
    class Procedure SetA(AValue : Integer); static;
  end;

Class Function TA.GetA : Integer;

begin
  Result:=myprivateA;
end;

Class Procedure TA.SetA(AValue : integer);

begin
  myprivateA:=AValue;
end;

begin
  TA.SetA(123);
  Writeln(TA.MyPrivateA);
end.
```

Which will output 123, when run.

In the implementation of a static class method, the `Self` identifier is not available. The method behaves as if `Self` is hardcoded to the declared class, not the actual class with which it was called. In regular class methods, `Self` contains the Actual class for which the method was called. The following example makes this clear:

```
Type
  TA = Class
    Class procedure DoIt; virtual;
    Class Procedure DoitStatic; static;
  end;

  TB = Class(TA)
    Class procedure DoIt; override;
  end;

Class procedure TA.DOit;

begin
```

```
    Writeln('TA.Doit : ',Self.ClassName);
end;

Class procedure TA.DoitStatic;

begin
    Doit;
    Writeln('TA.DoitStatic : ',ClassName);
end;

Class procedure TB.DoIt;

begin
    Inherited;
    Writeln('TB.Doit : ',Self.ClassName);
end;

begin
    Writeln('Through static method:');
    TB.DoItStatic;
    Writeln('Through class method:');
    TB.Doit;
end.
```

When run, this example will print:

```
Through static method:
TA.Doit : TA
TA.DoitStatic : TA
Through class method:
TA.Doit : TB
TB.Doit : TB
```

For the static class method, even though it was called using TB, the class (*Self*, if it were available) is set to TA, the class in which the static method was defined. For the class method, the class is set to the actual class used to call the method (TB).

### 6.4.7 Message methods

New in classes are *message methods*. Pointers to message methods are stored in a special table, together with the integer or string constant that they were declared with. They are primarily intended to ease programming of callback functions in several GUI toolkits, such as Win32 or GTK. In difference with Delphi, Free Pascal also accepts strings as message identifiers. Message methods are always virtual.

As can be seen in the class declaration diagram, message methods are declared with a *Message* keyword, followed by an integer constant expression.

Additionally, they can take only one var argument (typed or not):

```
Procedure TMyObject.MyHandler(Var Msg); Message 1;
```

The method implementation of a message function is not different from an ordinary method. It is also possible to call a message method directly, but this should not be done. Instead, the `TObject.Dispatch`

method should be used. Message methods are automatically virtual, i.e. they can be overridden in descendent classes.

The `TObject.Dispatch` method can be used to call a message handler. It is declared in the **system** unit and will accept a `var` parameter which must have at the first position a cardinal with the message ID that should be called. For example:

```
Type
  TMsg = Record
    MSGID : Cardinal;
    Data : Pointer;
Var
  Msg : TMsg;

MyObject.Dispatch (Msg);
```

In this example, the `Dispatch` method will look at the object and all its ancestors (starting at the object, and searching up the inheritance class tree), to see if a message method with message `MSGID` has been declared. If such a method is found, it is called, and passed the `Msg` parameter.

If no such method is found, `DefaultHandler` is called. `DefaultHandler` is a virtual method of `TObject` that doesn't do anything, but which can be overridden to provide any processing that might be needed. `DefaultHandler` is declared as follows:

```
procedure DefaultHandler(var message);virtual;
```

In addition to the message method with a `Integer` identifier, Free Pascal also supports a message method with a string identifier:

```
Procedure TMyObject.MyStrHandler(Var Msg); Message 'OnClick';
```

The working of the string message handler is the same as the ordinary integer message handler:

The `TObject.DispatchStr` method can be used to call a message handler. It is declared in the **system** unit and will accept one parameter which must have at the first position a short string with the message ID that should be called. For example:

```
Type
  TMsg = Record
    MsgStr : String[10]; // Arbitrary length up to 255 characters.
    Data : Pointer;
Var
  Msg : TMsg;

MyObject.DispatchStr (Msg);
```

In this example, the `DispatchStr` method will look at the object and all its ancestors (starting at the object, and searching up the inheritance class tree), to see if a message method with message `MsgStr` has been declared. If such a method is found, it is called, and passed the `Msg` parameter.

If no such method is found, `DefaultHandlerStr` is called. `DefaultHandlerStr` is a virtual method of `TObject` that doesn't do anything, but which can be overridden to provide any processing that might be needed. `DefaultHandlerStr` is declared as follows:

```
procedure DefaultHandlerStr(var message);virtual;
```

In addition to this mechanism, a string message method accepts a `self` parameter:

```
Procedure StrMsgHandler(Data: Pointer;  
                        Self: TMyObject); Message 'OnClick';
```

When encountering such a method, the compiler will generate code that loads the `Self` parameter into the object instance pointer. The result of this is that it is possible to pass `Self` as a parameter to such a method.

**Remark:** The type of the `Self` parameter must be of the same class as the class the method is defined in.

### 6.4.8 Using inherited

In an overridden virtual method, it is often necessary to call the parent class' implementation of the virtual method. This can be done with the `inherited` keyword. Likewise, the `inherited` keyword can be used to call any method of the parent class.

The first case is the simplest:

```
Type  
  TMyClass = Class(TComponent)  
    Constructor Create(AOwner : TComponent); override;  
  end;  
  
Constructor TMyClass.Create(AOwner : TComponent);  
  
begin  
  Inherited;  
  // Do more things  
end;
```

In the above example, the `Inherited` statement will call `Create` of `TComponent`, passing it `AOwner` as a parameter: the same parameters that were passed to the current method will be passed to the parent's method. They must not be specified again: if none are specified, the compiler will pass the same arguments as the ones received.

The second case is slightly more complicated:

```
Type  
  TMyClass = Class(TComponent)  
    Constructor Create(AOwner : TComponent); override;  
    Constructor CreateNew(AOwner : TComponent; DoExtra : Boolean);  
  end;  
  
Constructor TMyClass.Create(AOwner : TComponent);  
begin  
  Inherited;  
end;  
  
Constructor TMyClass.CreateNew(AOwner : TComponent; DoExtra : Boolean);  
begin  
  Inherited Create(AOwner);  
  // Do stuff  
end;
```

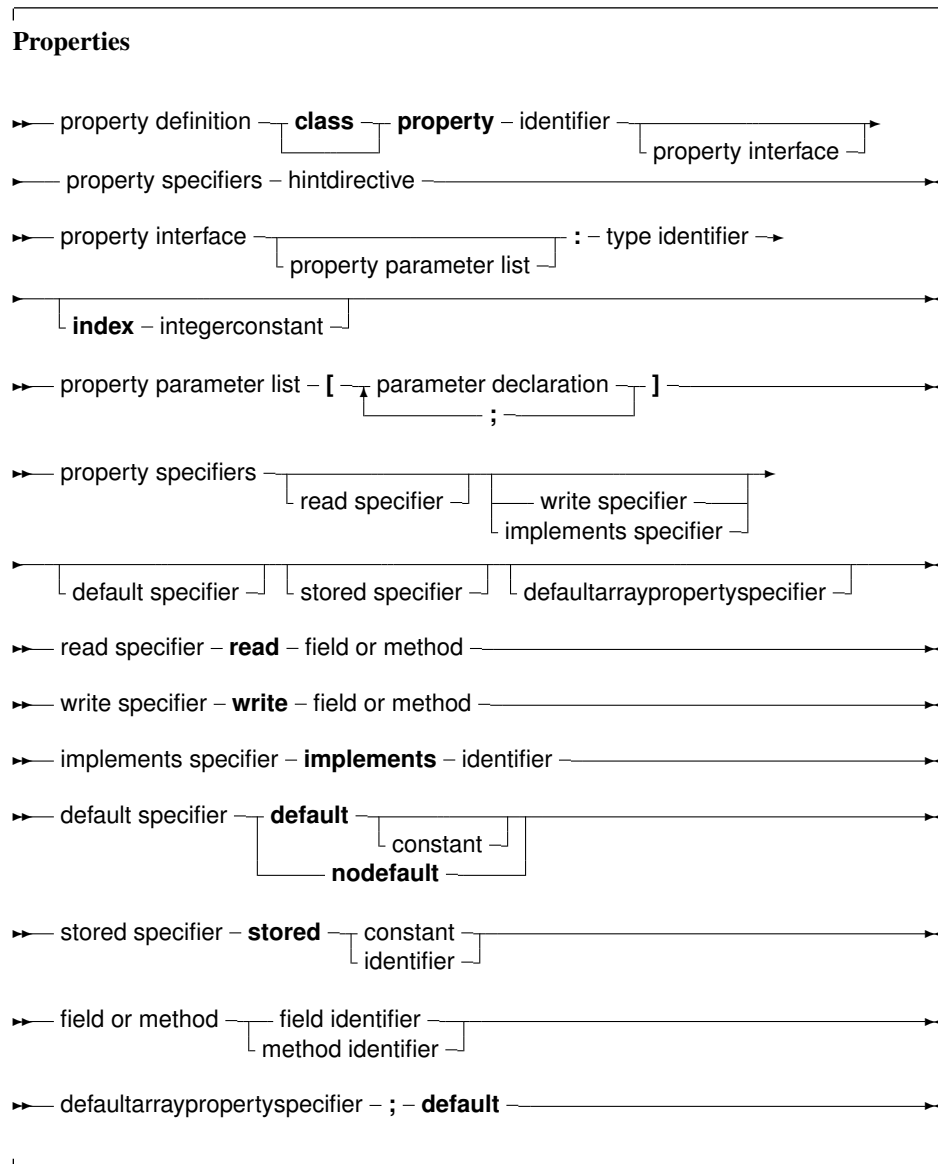

The `CreateNew` method will first call `TComponent.Create` and will pass it `AOwner` as a parameter. It will not call `TMyClass.Create`.

Although the examples were given using constructors, the use of `inherited` is not restricted to constructors, it can be used for any procedure or function or destructor as well.

## 6.5 Properties

### 6.5.1 Definition

Classes can contain properties as part of their fields list. A property acts like a normal field, i.e. its value can be retrieved or set, but it allows to redirect the access of the field through functions and procedures. They provide a means to associate an action with an assignment of or a reading from a class 'field'. This allows e.g. checking that a value is valid when assigning, or, when reading, it allows to construct the value on the fly. Moreover, properties can be read-only or write only. The prototype declaration of a property is as follows:

A `read specifier` is either the name of a field that contains the property, or the name of a method function that has the same return type as the property type. In the case of a simple type, this function must not accept an argument. In case of an array property, the function must accept a single argument of the same type as the index. In case of an indexed property, it must accept an integer as an argument.

A `read specifier` is optional, making the property write-only. Note that class methods cannot be used as `read specifiers`.

A `write specifier` is optional: If there is no `write specifier`, the property is read-only. A `write specifier` is either the name of a field, or the name of a method procedure that accepts as a sole argument a variable of the same type as the property. In case of an array property, the procedure must accept 2 arguments: the first argument must have the same type as the index, the second argument must be of the same type as the property. Similarly, in case of an indexed property, the first parameter must be an integer.

The section (`private`, `published`) in which the specified function or procedure resides is irrelevant. Usually, however, this will be a protected or private method.

For example, given the following declaration:

```
Type
  MyClass = Class
    Private
      Field1 : Longint;
      Field2 : Longint;
      Field3 : Longint;
      Procedure Sety (value : Longint);
      Function Gety : Longint;
      Function Getz : Longint;
    Public
      Property X : Longint Read Field1 write Field2;
      Property Y : Longint Read GetY Write Sety;
      Property Z : Longint Read GetZ;
    end;

Var
  MyClass : TMyClass;
```

The following are valid statements:

```
WriteLn ('X : ', MyClass.X);
WriteLn ('Y : ', MyClass.Y);
WriteLn ('Z : ', MyClass.Z);
MyClass.X := 0;
MyClass.Y := 0;
```

But the following would generate an error:

```
MyClass.Z := 0;
```

because Z is a read-only property.

What happens in the above statements is that when a value needs to be read, the compiler inserts a call to the various `getNNN` methods of the object, and the result of this call is used. When an assignment is made, the compiler passes the value that must be assigned as a parameter to the various `setNNN` methods.

Because of this mechanism, properties cannot be passed as var arguments to a function or procedure, since there is no known address of the property (at least, not always).

### 6.5.2 Indexed properties

If the property definition contains an index, then the read and write specifiers must be a function and a procedure. Moreover, these functions require an additional parameter : An integer parameter. This allows to read or write several properties with the same function. For this, the properties must have the same type. The following is an example of a property with an index:

```
{ $mode objfpc }
Type
  TPoint = Class(TObject)
  Private
    FX, FY : Longint;
    Function GetCoord (Index : Integer): Longint;
    Procedure SetCoord (Index : Integer; Value : longint);
  Public
    Property X : Longint index 1 read GetCoord Write SetCoord;
    Property Y : Longint index 2 read GetCoord Write SetCoord;
    Property Coords[Index : Integer]:Longint Read GetCoord;
  end;

Procedure TPoint.SetCoord (Index : Integer; Value : Longint);
begin
  Case Index of
    1 : FX := Value;
    2 : FY := Value;
  end;
end;

Function TPoint.GetCoord (INdex : Integer) : Longint;
begin
  Case Index of
    1 : Result := FX;
    2 : Result := FY;
  end;
end;

Var
  P : TPoint;

begin
  P := TPoint.create;
  P.X := 2;
  P.Y := 3;
  With P do
    WriteLn ('X=', X, ' Y=', Y);
  end.
```

When the compiler encounters an assignment to X, then `SetCoord` is called with as first parameter the index (1 in the above case) and with as a second parameter the value to be set. Conversely, when reading the value of X, the compiler calls `GetCoord` and passes it index 1. Indexes can only be integer values.

### 6.5.3 Array properties

Array properties also exist. These are properties that accept an index, just as an array does. The index can be one-dimensional, or multi-dimensional. In difference with normal (static or dynamic) arrays, the index of an array property doesn't have to be an ordinal type, but can be any type.

A `read` specifier for an array property is the name method function that has the same return type as the property type. The function must accept as a sole argument a variable of the same type as the index type. For an array property, one cannot specify fields as `read` specifiers.

A `write` specifier for an array property is the name of a method procedure that accepts two arguments: the first argument has the same type as the index, and the second argument is a parameter of the same type as the property type. As an example, see the following declaration:

```
Type
  TIntList = Class
  Private
    Function GetInt (I : Longint) : longint;
    Function GetAsString (A : String) : String;
    Procedure SetInt (I : Longint; Value : Longint;);
    Procedure SetAsString (A : String; Value : String);
  Public
    Property Items [i : Longint] : Longint Read GetInt
                                                Write SetInt;
    Property StrItems [S : String] : String Read GetAsString
                                                Write SetAsString;
  end;

Var
  AIntList : TIntList;
```

Then the following statements would be valid:

```
AIntList.Items[26] := 1;
AIntList.StrItems['twenty-five'] := 'zero';
WriteLn ('Item 26 : ',AIntList.Items[26]);
WriteLn ('Item 25 : ',AIntList.StrItems['twenty-five']);
```

While the following statements would generate errors:

```
AIntList.Items['twenty-five'] := 1;
AIntList.StrItems[26] := 'zero';
```

Because the index types are wrong.

Array properties can be multi-dimensional:

```
Type
  TGrid = Class
  Private
    Function GetCell (I,J : Longint) : String;
    Procedure SetCell (I,J : Longint; Value : String);
  Public
    Property Cellcs [Row,Col : Longint] : String Read GetCell
                                                Write SetCell;
  end;
```

If there are N dimensions, then the types of the first N arguments of the getter and setter must correspond to the types of the N index specifiers in the array property definition.

### 6.5.4 Default properties

Array properties can be declared as `default` properties. This means that it is not necessary to specify the property name when assigning or reading it. In the previous example, if the definition of the `items` property would have been

```
Property Items[i : Longint]: Longint Read GetInt
                                Write SetInt; Default;
```

Then the assignment

```
AIntList.Items[26] := 1;
```

Would be equivalent to the following abbreviation.

```
AIntList[26] := 1;
```

Only one default property per class is allowed, but descendent classes can redeclare the default property.

### 6.5.5 Storage information

The *stored specifier* should be either a boolean constant, a boolean field of the class, or a parameter-less function which returns a boolean result. This specifier has no result on the class behaviour. It is an aid for the streaming system: the stored specifier is specified in the RTTI generated for a class (it can only be streamed if RTTI is generated), and is used to determine whether a property should be streamed or not: it saves space in a stream. It is not possible to specify the 'Stored' directive for array properties.

The *default specifier* can be specified for ordinal types and sets. It serves the same purpose as the *stored specifier*: properties that have as value their default value, will not be written to the stream by the streaming system. The default value is stored in the RTTI that is generated for the class. Note that

1. When the class is instantiated, the default value is not automatically applied to the property, it is the responsibility of the programmer to do this in the constructor of the class.
2. The value 2147483648 cannot be used as a default value, as it is used internally to denote `nodefault`.
3. It is not possible to specify a default for array properties.

The *nodefault specifier* (`nodefault`) must be used to indicate that a property has no default value. The effect is that the value of this property is always written to the stream when streaming the property.

### 6.5.6 Overriding properties

Properties can be overridden in descendent classes, just like methods. The difference is that for properties, the overriding can always be done: properties should not be marked 'virtual' so they can be overridden, they are always overridable (in this sense, properties are always 'virtual'). The type of the overridden property does not have to be the same as the parents class property type.

Since they can be overridden, the keyword 'inherited' can also be used to refer to the parent definition of the property. For example consider the following code:

```
type
  TAncestor = class
  private
    FP1 : Integer;
  public
    property P: integer Read FP1 write FP1;
  end;

  TClassA = class(TAncestor)
  private
    procedure SetP(const AValue: char);
    function getP : Char;
  public
    constructor Create;
    property P: char Read GetP write SetP;
  end;

procedure TClassA.SetP(const AValue: char);

begin
  Inherited P:=Ord(AValue);
end;

procedure TClassA.GetP : char;

begin
  Result:=Char((Inherited P) and $FF);
end;
```

TClassA redefines P as a character property instead of an integer property, but uses the parents P property to store the value.

Care must be taken when using virtual get/set routines for a property: setting the inherited property still observes the normal rules of inheritance for methods. Consider the following example:

```
type
  TAncestor = class
  private
    procedure SetP1(const AValue: integer); virtual;
  public
    property P: integer write SetP1;
  end;

  TClassA = class(TAncestor)
  private
    procedure SetP1(const AValue: integer); override;
    procedure SetP2(const AValue: char);
  public
    constructor Create;
    property P: char write SetP2;
  end;

constructor TClassA.Create;
begin
  inherited P:=3;
```

```
end;
```

In this case, when setting the inherited property `P`, the implementation `TClassA.SetP1` will be called, because the `SetP1` method is overridden.

If the parent class implementation of `SetP1` must be called, then this must be called explicitly:

```
constructor TClassA.Create;  
begin  
    inherited SetP1(3);  
end;
```

## 6.6 Class properties

Class properties are very much like global property definitions. They are associated with the class, not with an instance of the class.

A consequence of this is that the storage for the property value must be a class var, not a regular field or variable of the class: normal fields or variables are stored in an instance of the class.

Class properties can have a getter and setter method like regular properties, but these must be static methods of the class.

That means that the following contains a valid class property definition:

```
TA = Class(TObject)  
Private  
    class var myprivatea : integer;  
    class Function GetB : Integer; static;  
    class Procedure SetA(AValue : Integer); static;  
    class Procedure SetB(AValue : Integer); static;  
public  
    Class property MyA : Integer Read MyPrivateA Write SetA;  
    Class property MyA : Integer Read GetB Write SetB;  
end;
```

The reason for the requirement is that a class property is associated to the particular class in which it is defined, but not to descendent classes. Since class methods can be virtual, this would allow descendent classes to override the method, making them unsuitable for class property access.

## 6.7 Nested types, constants and variables

A class definition can contain a type section, const section and a variable section. The type and constant sections act as a regular type section as found in a unit or method/function/procedure implementation. The variables act as regular fields of the class, unless they are in a `class var` section, in which case they act as if they were defined at the unit level, within the namespace of the class.

However, the visibility of these sections does play a role: private and protected (strict or not) constants, types and variables can only be used as far as their visibility allows.

Public types can be used outside the class, by their full name:

```
type  
    TA = Class(TObject)  
    Public
```

```
    Type TEnum = (a,b,c);
    Class Function DoSomething : TEnum;
end;

Class Function TA.DoSomething : TEnum;

begin
    Result:=a;
end;

var
    E : TA.TEnum;

begin
    E:=TA.DoSomething;
end.
```

**Whereas**

```
type
    TA = Class(TObject)
    Strict Private
        Type TEnum = (a,b,c);
    Public
        Class Function DoSomething : TEnum;
    end;

Class Function TA.DoSomething : TEnum;

begin
    Result:=a;
end;

var
    E : TA.TEnum;

begin
    E:=TA.DoSomething;
end.
```

**Will not compile and will return an error:**

```
tt.pp(20,10) Error: identifier idents no member "TEnum"
```

## Chapter 7

# Interfaces

### 7.1 Definition

As of version 1.1, FPC supports interfaces. Interfaces are an alternative to multiple inheritance (where a class can have multiple parent classes) as implemented for instance in C++. An interface is basically a named set of methods and properties: a class that *implements* the interface provides *all* the methods as they are enumerated in the Interface definition. It is not possible for a class to implement only part of the interface: it is all or nothing.

Interfaces can also be ordered in a hierarchy, exactly as classes: an interface definition that inherits from another interface definition contains all the methods from the parent interface, as well as the methods explicitly named in the interface definition. A class implementing an interface must then implement all members of the interface as well as the methods of the parent interface(s).

An interface can be uniquely identified by a GUID. GUID is an acronym for Globally Unique Identifier, a 128-bit integer guaranteed always to be unique<sup>1</sup>. Especially on Windows systems, the GUID of an interface can and must be used when using COM.

The definition of an Interface has the following form:

Along with this definition the following must be noted:

- Interfaces can only be used in DELPHI mode or in OBJFPC mode.
- There are no visibility specifiers. All members are public (indeed, it would make little sense to make them private or protected).

<sup>1</sup>In theory, of course.

- The properties declared in an interface can only have methods as read and write specifiers.
- There are no constructors or destructors. Instances of interfaces cannot be created directly: instead, an instance of a class implementing the interface must be created.
- Only calling convention modifiers may be present in the definition of a method. Modifiers as `virtual`, `abstract` or `dynamic`, and hence also `override` cannot be present in the interface definition.

The following are examples of interfaces:

```
IUnknown = interface ['{00000000-0000-0000-C000-000000000046}']
  function QueryInterface(const iid : tguid;out obj) : longint;
  function _AddRef : longint;
  function _Release : longint;
end;
IInterface = IUnknown;

IMyInterface = Interface
  Function MyFunc : Integer;
  Function MySecondFunc : Integer;
end;
```

As can be seen, the GUID identifying the interface is optional.

## 7.2 Interface identification: A GUID

An interface can be identified by a GUID. This is a 128-bit number, which is represented in a text representation (a string literal):

```
[ '{HHHHHHHHH-HHHH-HHHH-HHHH-HHHHHHHHHHHH}' ]
```

Each H character represents a hexadecimal number (0-9,A-F). The format contains 8-4-4-4-12 numbers. A GUID can also be represented by the following record, defined in the `objpas` unit (included automatically when in DELPHI or OBJFPC mode):

```
PGuid = ^TGuid;
TGuid = packed record
  case integer of
    1 : (
      Data1 : DWord;
      Data2 : word;
      Data3 : word;
      Data4 : array[0..7] of byte;
    );
    2 : (
      D1 : DWord;
      D2 : word;
      D3 : word;
      D4 : array[0..7] of byte;
    );
    3 : ( { uuid fields according to RFC4122 }
      time_low : dword;
```

```
        time_mid : word;  
        time_hi_and_version : word;  
        clock_seq_hi_and_reserved : byte;  
        clock_seq_low : byte;  
        node : array[0..5] of byte;  
    );  
end;
```

A constant of type TGUID can be specified using a string literal:

```
{ $mode objfpc }  
program testuid;  
  
Const  
    MyGUID : TGUID = '{10101010-1010-0101-1001-110110110110}';  
  
begin  
end.
```

Normally, the GUIDs are only used in Windows, when using COM interfaces. More on this in the next section.

## 7.3 Interface implementations

When a class implements an interface, it should implement all methods of the interface. If a method of an interface is not implemented, then the compiler will give an error. For example:

```
Type  
    IMyInterface = Interface  
        Function MyFunc : Integer;  
        Function MySecondFunc : Integer;  
    end;  
  
    TMyClass = Class(TInterfacedObject, IMyInterface)  
        Function MyFunc : Integer;  
        Function MyOtherFunc : Integer;  
    end;  
  
Function TMyClass.MyFunc : Integer;  
  
begin  
    Result:=23;  
end;  
  
Function TMyClass.MyOtherFunc : Integer;  
  
begin  
    Result:=24;  
end;
```

will result in a compiler error:

```
Error: No matching implementation for interface method  
"IMyInterface.MySecondFunc:LongInt" found
```

Normally, the names of the methods that implement an interface, must equal the names of the methods in the interface definition.

However, it is possible to provide aliases for methods that make up an interface: that is, the compiler can be told that a method of an interface is implemented by an existing method with a different name. This is done as follows:

```
Type
  IMyInterface = Interface
    Function MyFunc : Integer;
  end;

  TMyClass = Class(TInterfacedObject, IMyInterface)
    Function MyOtherFunction : Integer;
    Function IMyInterface.MyFunc = MyOtherFunction;
  end;
```

This declaration tells the compiler that the `MyFunc` method of the `IMyInterface` interface is implemented in the `MyOtherFunction` method of the `TMyClass` class.

## 7.4 Interface delegation

Sometimes, the methods of an interface are implemented by a helper (or delegate) object, or the class instance has obtained an interface pointer for this interface and that should be used. This can be for instance when an interface must be added to a series of totally unrelated classes: the needed interface functionality is added to a separate class, and each of these classes uses an instance of the helper class to implement the functionality.

In such a case, it is possible to instruct the compiler that the interface is not implemented by the object itself, but actually resides in a helper class or interface. This can be done with the `implements` property modifier.

If the class has a pointer to the desired interface, the following will instruct the compiler that when the `IMyInterface` interface is requested, it should use the reference in the field:

```
type
  IMyInterface = interface
    procedure P1;
  end;

  TMyClass = class(TInterfacedObject, IMyInterface)
  private
    FMyInterface: IMyInterface; // interface type
  public
    property MyInterface: IMyInterface
      read FMyInterface implements IMyInterface;
  end;
```

The interface should not necessarily be in a field, any read identifier can be used.

If the interface is implemented by a delegate object, (a helper object that actually implements the interface) then it can be used as well with the `implements` keyword:

```
{$interfaces corba}
type
```

```
IMyInterface = interface
    procedure P1;
end;

// NOTE: Interface must be specified here
TDelegateClass = class(TObject, IMyInterface)
private
    procedure P1;
end;

TMyClass = class(TInterfacedObject, IMyInterface)
private
    FMyInterface: TDelegateClass; // class type
    property MyInterface: TDelegateClass
        read FMyInterface implements IMyInterface;
end;
```

Note that in difference with Delphi, the delegate class must explicitly specify the interface: the compiler will not search for the methods in the delegate class, it will simply check if the delegate class implements the specified interface.

It is not possible to mix method resolution and interface delegation. That means, it is not possible to implement part of an interface through method resolution and implement part of the interface through delegation. The following attempts to implement `IMyInterface` partly through method resolution (`P1`), and partly through delegation. The compiler will not accept the following code:

```
{$interfaces corba}
type
    IMyInterface = interface
        procedure P1;
        procedure P2;
    end;

    TMyClass = class(TInterfacedObject, IMyInterface)
        FI : IMyInterface;
    protected
        procedure IMyInterface.P1 = MyP1;
        procedure MyP1;
        property MyInterface: IMyInterface read FI implements IMyInterface;
    end;
```

The compiler will throw an error:

```
Error: Interface "IMyInterface" can't be delegated by "TMyClass",
it already has method resolutions
```

However, it is possible to implement one interface through method resolution, and another through delegation:

```
{$interfaces corba}
type
    IMyInterface = interface
        procedure P1;
    end;
```

```
IMyInterface2 = interface
  procedure P2;
end;

TMyClass = class(TInterfacedObject,
                 IMyInterface, IMyInterface2)
  FI2 : IMyInterface2;
protected
  procedure IMyInterface.P1 = MyP1;
  procedure MyP1;
public
  property MyInterface: IMyInterface2
    read FI2 implements IMyInterface2;
end;
```

## 7.5 Interfaces and COM

When using interfaces on Windows which should be available to the COM subsystem, the calling convention should be `stdcall` - this is not the default Free Pascal calling convention, so it should be specified explicitly.

COM does not know properties. It only knows methods. So when specifying property definitions as part of an interface definition, be aware that the properties will only be known in the Free Pascal compiled program: other Windows programs will not be aware of the property definitions.

## 7.6 CORBA and other Interfaces

COM is not the only architecture where interfaces are used. CORBA knows interfaces, UNO (the OpenOffice API) uses interfaces, and Java as well. These languages do not know the `IUnknown` interface used as the basis of all interfaces in COM. It would therefore be a bad idea if an interface automatically descended from `IUnknown` if no parent interface was specified. Therefore, a directive `{ $INTERFACES }` was introduced in Free Pascal: it specifies what the parent interface is of an interface, declared without parent. More information about this directive can be found in the [Programmer's Guide](#).

Note that COM interfaces are by default reference counted, because they descend from `IUnknown`.

Corba interfaces are identified by a simple string so they are assignment compatible with strings and not with `TGUID`. The compiler does not do any automatic reference counting for the CORBA interfaces, so the programmer is responsible for any reference bookkeeping.

## 7.7 Reference counting

All COM interfaces use reference counting. This means that whenever an interface is assigned to a variable, its reference count is updated. Whenever the variable goes out of scope, the reference count is automatically decreased. When the reference count reaches zero, usually the instance of the class that implements the interface, is freed.

Care must be taken with this mechanism. The compiler may or may not create temporary variables when evaluating expressions, and assign the interface to a temporary variable, and only then assign the temporary variable to the actual result variable. No assumptions should be made about the number

of temporary variables or the time when they are finalized - this may (and indeed does) differ from the way other compilers (e.g. Delphi) handle expressions with interfaces. E.g. a type cast is also an expression:

```
Var
  B : AClass;

begin
  // ...
  AInterface(B.Intf).testproc;
  // ...
end;
```

Assume the interface `intf` is reference counted. When the compiler evaluates `B.Intf`, it creates a temporary variable. This variable may be released only when the procedure exits: it is therefore invalid to e.g. free the instance `B` prior to the exit of the procedure, since when the temporary variable is finalized, it will attempt to free `B` again.

## Chapter 8

# Generics

### 8.1 Introduction

Generics are templates for generating classes. It is a concept that comes from C++, where it is deeply integrated in the language. As of version 2.2, Free Pascal also officially has support for templates or Generics. They are implemented as a kind of macro which is stored in the unit files that the compiler generates, and which is replayed as soon as a generic class is specialized.

Currently, only generic classes can be defined. Later, support for generic records, functions and arrays may be introduced.

Creating and using generics is a 2-phase process.

1. The definition of the generic class is defined as a new type: this is a code template, a macro which can be replayed by the compiler at a later stage.
2. A generic class is specialized: this defines a second class, which is a specific implementation of the generic class: the compiler replays the macro which was stored when the generic class was defined.

### 8.2 Generic class definition

A generic class definition is much like a class definition, with the exception that it contains a list of placeholders for types, and can contain a series of local variable blocks or local type blocks, as can be seen in the following syntax diagram:

The generic class declaration should be followed by a class implementation. It is the same as a normal class implementation with a single exception, namely that any identifier with the same name as one of the template identifiers must be a type identifier.

The generic class declaration is much like a normal class declaration, except for the local variable and local type block. The local type block defines types that are type placeholders: they are not actualized until the class is specialized.

The local variable block is just an alternate syntax for ordinary class fields. The reason for introducing is the introduction of the `Type` block: just as in a unit or function declaration, a class declaration can now have a local type and variable block definition.

The following is a valid generic class definition:

```
Type
generic TList<_T>=class(TObject)
  type public
    TCompareFunc = function(const Item1, Item2: _T): Integer;
  var public
    data : _T;
    procedure Add(item: _T);
    procedure Sort(compare: TCompareFunc);
end;
```

This class could be followed by an implementation as follows:

```
procedure TList.Add(item: _T);
begin
  data:=item;
end;

procedure TList.Sort(compare: TCompareFunc);
begin
  if compare(data, 20) <= 0 then
    halt(1);
end;
```

There are some noteworthy things about this declaration and implementation:

1. There is a single placeholder `_T`. It will be substituted by a type identifier when the generic class is specialized. The identifier `_T` may not be used for anything else than a placeholder. This means that the following would be invalid:

```
procedure TList.Sort(compare: TCompareFunc);

Var
  _t : integer;

begin
```

```
// do something.
end;
```

2. The local type block contains a single type `TCompareFunc`. Note that the actual type is not yet known inside the generic class definition: the definition contains a reference to the placeholder `_T`. All other identifier references must be known when the generic class is defined, *not* when the generic class is specialized.
3. The local variable block is equivalent to the following:

```
generic TList<_T>=class(TObject)
  type public
    TCompareFunc = function(const Item1, Item2: _T): Integer;
Public
  data : _T;
  procedure Add(item: _T);
  procedure Sort(compare: TCompareFunc);
end;
```

4. Both the local variable block and local type block have a visibility specifier. This is optional; if it is omitted, the current visibility is used.

### 8.3 Generic class specialization

Once a generic class is defined, it can be used to generate other classes: this is like replaying the definition of the class, with the template placeholders filled in with actual type definitions.

This can be done in any Type definition block. The specialized type looks as follows:

Which is a very simple definition. Given the declaration of `TList` in the previous section, the following would be a valid type definition:

```
Type
  TPointerList = specialize TList<Pointer>;
  TIntegerList = specialize TList<Integer>;
```

The following is not allowed:

```
Var
  P : specialize TList<Pointer>;
```

that is, a variable cannot be directly declared using a specialization.

The type in the specialize statement must be known. Given the 2 generic class definitions:

```
type
  Generic TMyFirstType<T1> = Class (TMyObject);
  Generic TMySecondType<T2> = Class (TMyOtherObject);
```

Then the following specialization is not valid:

```
type
  TMySpecialType = specialize TMySecondType<TMyFirstType>;
```

because the type `TMyFirstType` is a generic type, and thus not fully defined. However, the following is allowed:

```
type
  TA = specialize TMyFirstType<Atype>;
  TB = specialize TMySecondType<TA>;
```

because `TA` is already fully defined when `TB` is specialized.

Note that 2 specializations of a generic type with the same types in a placeholder are not assignment compatible. In the following example:

```
type
  TA = specialize TList<Pointer>;
  TB = specialize TList<Pointer>;
```

variables of types `TA` and `TB` cannot be assigned to each other, i.e the following assignment will be invalid:

```
Var
  A : TA;
  B : TB;

begin
  A:=B;
```

**Remark:** It is not possible to make a forward definition of a generic class. The compiler will generate an error if a forward declaration of a class is later defined as a generic specialization.

## 8.4 A word about type compatibility

Whenever a generic class is specialized, this results in a new, distinct type. These types are assignment compatible.

Take the following generic definition:

```
unit ua;

interface

type
  Generic TMyClass<T> = Class (TObject)
    Procedure DoSomething(A : T; B : Integer);
  end;
```

Implementation

```
Procedure TMyClass.DoSomething(A : T; B : Integer);  
  
begin  
    // Some code.  
end;  
  
end.
```

And the following specializations:

```
unit ub;  
  
interface  
  
uses ua;  
  
Type  
    TB = Specialize TMyClass<string>;  
  
implementation  
  
end.
```

the following specializations is identical, but appears in a different unit:

```
unit uc;  
  
interface  
  
uses ua;  
  
Type  
    TB = Specialize TMyClass<string>;  
  
implementation  
  
end.
```

The following will then compile:

```
unit ud;  
  
interface  
  
uses ua,ub,uc;  
  
Var  
    B : ub.TB;  
    C : uc.TB;  
  
implementation
```

```
begin
  B:=C;
end.
```

The types `ub.TB` and `uc.TB` are assignment compatible. It does not matter that the types are defined in different units. They could be defined in the same unit as well:

```
unit ue;

interface

uses ua;

Type
  TB = Specialize TMyClass<string>;
  TC = Specialize TMyClass<string>;

Var
  B : TB;
  C : TC;

implementation

begin
  B:=C;
end.
```

Each specialization of a generic class with the same types as parameters is a new, distinct type, but these types are assignment compatible.

If the specialization is with a different type as parameters, the types are still distinct, but no longer assignment compatible. i.e. the following will not compile:

```
unit uf;

interface

uses ua;

Type
  TB = Specialize TMyClass<string>;
  TC = Specialize TMyClass<integer>;

Var
  B : TB;
  C : TC;

implementation

begin
  B:=C;
end.
```

When compiling, an error will result:

```
Error: Incompatible types: got "TMyClass$1$crc31B95292"
expected "TMyClass$1$crc1ED6E3D5"
```

## 8.5 A word about scope

It should be stressed that all identifiers other than the template placeholders should be known when the generic class is declared. This works in 2 ways. First, all types must be known, that is, a type identifier with the same name must exist. The following unit will produce an error:

```
unit myunit;

interface

type
  Generic TMyClass<T> = Class(TObject)
    Procedure DoSomething(A : T; B : TSomeType);
  end;

Type
  TSomeType = Integer;
  TSomeTypeClass = specialize TMyClass<TSomeType>;

Implementation

Procedure TMyClass.DoSomething(A : T; B : TSomeType);

begin
  // Some code.
end;

end.
```

The above code will result in an error, because the type `TSomeType` is not known when the declaration is parsed:

```
home: >fpc myunit.pp
myunit.pp(8,47) Error: Identifier not found "TSomeType"
myunit.pp(11,1) Fatal: There were 1 errors compiling module, stopping
```

The second way in which this is visible, is the following. Assume a unit

```
unit mya;

interface

type
  Generic TMyClass<T> = Class(TObject)
    Procedure DoSomething(A : T);
  end;

Implementation
```

```
Procedure DoLocalThings;

begin
  Writeln('mya.DoLocalThings');
end;

Procedure TMyClass.DoSomething(A : T);

begin
  DoLocalThings;
end;

end.
```

**and a program**

```
program myb;

uses mya;

procedure DoLocalThings;

begin
  Writeln('myb.DoLocalThings');
end;

Type
  TB = specialize TMyClass<Integer>;

Var
  B : TB;

begin
  B:=TB.Create;
  B.DoSomething(1);
end.
```

Despite the fact that generics act as a macro which is replayed at specialization time, the reference to `DoLocalThings` is resolved when `TMyClass` is defined, not when `TB` is defined. This means that the output of the program is:

```
home: >fpc -S2 myb.pp
home: >myb
mya.DoLocalThings
```

This is dictated by safety and necessity:

1. A programmer specializing a class has no way of knowing which local procedures are used, so he cannot accidentally 'override' it.
2. A programmer specializing a class has no way of knowing which local procedures are used, so he cannot implement it either, since he does not know the parameters.

3. If implementation procedures are used as in the example above, they cannot be referenced from outside the unit. They could be in another unit altogether, and the programmer has no way of knowing he should include them before specializing his class.

## Chapter 9

# Extended records

### 9.1 Definition

Extended records are in many ways equivalent to objects and to a lesser extent to classes: they are records which have methods associated with them, and properties. Like objects, when defined as a variable they are allocated on the stack. They do not need to have a constructor. Extended records have limitations over objects and classes in that they do not allow inheritance and polymorphism. It is impossible to create a descendant record of a record<sup>1</sup>.

Why then introduce extended records ? They were introduced by Delphi 2005 to support one of the features introduced by .NET. Delphi deprecated the old TP style of objects, and re-introduced the features of .NET as extended records. Free Pascal aims to be Delphi compatible, so extended records are allowed in Free Pascal as well, but only in Delphi mode.

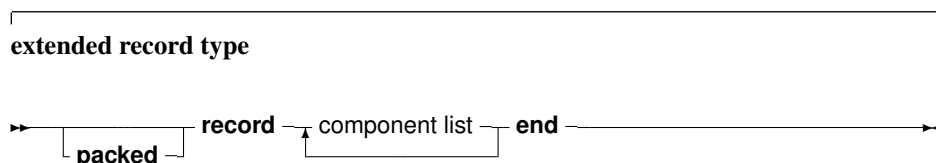

If extended records are desired in ObjFPC mode, then a mode switch must be used:

```
{ $mode objfpc }  
{ $modeswitch advancedrecords }
```

Compatibility is not the only reason for introducing extended records. There are some practical reasons for using methods or properties in records:

1. It is more in line with an object-oriented approach to programming: the type also contains any methods that work on it.
2. In contrast with a procedural approach, putting all operations that work on a record in the record itself, allows an IDE to show the available methods on the record when it is displaying code completion options.

Defining an extended record is much as defining an object or class:

<sup>1</sup>although it can be enhanced using record helpers, more about this in the chapter on record helpers.

Some of the restrictions when compared to classes or objects are obvious from the syntax diagram:

- No inheritance of records.
- No published section exists.
- Constructors or destructors cannot be defined.
- Class methods (if one can name them so) require the `static` keyword.
- Methods cannot be virtual or abstract - this is a consequence of the fact that there is no inheritance.

Other than that the definition much resembles that of a class or object.

The following are few examples of valid extended record definitions:

```
TTest1 = record
  a : integer;
  function Test(aRecurse: Boolean): Integer;
end;
```

```
TTest2 = record
  private
    A,b : integer;
  public
    procedure setA(AValue : integer);
    property SafeA : Integer Read A Write SetA;
end;
```

```
TTest3 = packed record
  private
    fA,fb : byte;
    procedure setA(AValue : Integer);
    function geta : integer;
  public
    property A : Integer Read GetA Write SetA;
end;
```

```
TTest4 = record
  private
    a : Integer;
  protected
    function getp : integer;
  public
    b : string;
    procedure setp (aValue : integer);
    property p : integer read Getp Write SetP;
  public
  case x : integer of
    1 : (Q : string);
    2 : (S : String);
  end;
```

Note that it is possible to specify a visibility for the members of the record. This is particularly useful for example when creating an interface to a C library: the actual fields can be declared hidden, and more 'pascal' like properties can be exposed which act as the actual fields. The `TTest3` record definition shows that the `packed` directive can be used in extended records. Extended records have the same memory layout as their regular counterparts: the methods and properties are not part of the record structure in memory.

The `TTest4` record definition in the above examples shows that the extended record still has the ability to define a variant part. As with the regular record, the variant part must come last. It cannot contain methods.

## 9.2 Extended record enumerators

Extended records can have an enumerator. To this end, a function returning an enumerator record must be defined in the extended record:

```
type
  TIntArray = array[0..3] of Integer;

  TEnumerator = record
  private
    FIndex: Integer;
    FArray: TIntArray;
    function GetCurrent: Integer;
  public
    function MoveNext: Boolean;
    property Current: Integer read GetCurrent;
  end;

  TMyArray = record
    F: array[0..3] of Integer;
    function GetEnumerator: TEnumerator;
  end;

function TEnumerator.MoveNext: Boolean;
begin
  inc(FIndex);
  Result := FIndex < Length(FArray);
```

```
end;

function TEnumerator.GetCurrent: Integer;
begin
    Result := FArray[FIndex];
end;

function TMyArray.GetEnumerator: TEnumerator;
begin
    Result.FArray := F;
    Result.FIndex := -1;
end;
```

After these definitions, the following code will compile and enumerate all elements in F:

```
var
    Arr: TMyArray;
    I: Integer;
begin
    for I in Arr do
        WriteLn(I);
    end.
```

The same effect can be achieved with the enumerator operator:

```
type
    TIntArray = array[0..3] of Integer;

    TEnumerator = record
    private
        FIndex: Integer;
        FArray: TIntArray;
        function GetCurrent: Integer;
    public
        function MoveNext: Boolean;
        property Current: Integer read GetCurrent;
    end;

    TMyArray = record
        F: array[0..3] of Integer;
    end;

function TEnumerator.MoveNext: Boolean;
begin
    inc(FIndex);
    Result := FIndex < Length(FArray);
end;

function TEnumerator.GetCurrent: Integer;
begin
    Result := FArray[FIndex];
end;

operator Enumerator(const A: TMyArray): TEnumerator;
```

```
begin
  Result.FArray := A.F;
  Result.FIndex := -1;
end;
```

This will allow the code to run as well.

## Chapter 10

# Class and record helpers

### 10.1 Definition

Class and record helpers can be used to add methods to an existing class or record, without making a derivation of the class or re-declaring the record. The effect is like inserting a method in the method table of the class. If the helper declaration is in the current scope of the code, then the methods and properties of the helper can be used as if they were part of the class declaration for the class or record that the helper extends.

The syntax diagram for a class or record helper is presented below.

The diagram shows that a helper definition looks very much like a regular class definition. It simply declares some extra constructors, methods, properties and fields for a class: the class or record type for which the helper is an extension is indicated after the `for` keyword. Since an enumerator for a class is obtained through a regular method, class helpers can also be used to override the enumerators.

As can be seen from the syntax diagram, it is possible to create descendents of helpers: the helpers can form a hierarchy of their own, allowing to override methods of a parent helper. They also have visibility specifiers, just like records and classes.

As in an instance of the class, the `Self` identifier in a method of a class helper refers to the class instance (not the helper instance). For a record, it refers to the record.

The following is a simple class helper for the `TObject` class, which provides an alternate version of the standard `ToString` method.

```
TObjectHelper = class helper for TObject
  function AsString(const aFormat: String): String;
end;
```

```
function TObjectHelper.AsString(const aFormat: String): String;
begin
    Result := Format(aFormat, [ToString]);
end;

var
    o: TObject;
begin
    Writeln(o.AsString('The object''s name is %s'));
end.
```

**Remark:** The helper modifier is only a modifier just after the `class` or `record` keywords. That means that the first member of a class or record cannot be named `helper`. A member of a class or record can be called `helper`, it just cannot be the first one, unless it is escaped with a `&`, as for all identifiers that match a keyword.

## 10.2 Restrictions on class helpers

It is not possible to extend a class with any method or property. There are some restrictions on the possibilities:

- Destructors or class destructors are not allowed.
- Class constructors are not allowed.
- Class helpers cannot descend from record helpers, and cannot extend record types.
- Field definitions are not allowed. Neither are class fields.
- Properties that refer to a field are not allowed. This is in fact a consequence of the previous item.
- Abstract methods are not allowed.
- Virtual methods of the class cannot be overridden. They can be hidden by giving them the same name or they can be overloaded using the `overload` directive.
- Unlike for regular procedures or methods, the `overload` specifier must be explicitly used when overloading methods from a class in a class helper. If `overload` is not used, the extended type's method is hidden by the helper method (as for regular classes).

The following modifies the previous example by overloading the `ToString` method:

```
TObjectHelper = class helper for TObject
    function ToString(const aFormat: String): String; overload;
end;

function TObjectHelper.ToString(const aFormat: String): String;
begin
    Result := Format(aFormat, [ToString]);
end;

var
    o: TObject;
begin
    Writeln(o.ToString('The object''s name is %s'));
end.
```

### 10.3 Restrictions on record helpers

Records do not offer the same possibilities as classes do. This reflects on the possibilities when creating record helpers. Below the restrictions on record helpers are enumerated:

- A record helper cannot be used to extend a class. The following will fail:

```
TTestHelper = record helper for TObject
end;
```

- Record helpers cannot implement constructors.
- Inside a helper's declaration the methods/fields of the extended record can't be accessed in e.g. a property definition. They can be accessed in the implementation, of course. This means that the following will not compile:

```
TTest = record
  Test: Integer;
end;

TTestHelper = record helper for TTest
  property AccessTest: Integer read Test;
end;
```

- Record helpers can only access public fields (in case an extended record with visibility specifiers is used).
- Inheritance of record helpers is only allowed in ObjFPC mode; In Delphi mode, it is not allowed.
- Record helpers can only descend from other record helpers, not from class helpers.
- Unlike class helpers, a descendent record helper must extend the same record type.
- In Delphi mode, it is not possible to call the extended record's method using `inherited`. It is possible to do so in ObjFPC mode. The following code needs ObjFPC mode to compile:

```
type
  TTest = record
    function Test(aRecurse: Boolean): Integer;
  end;

  TTestHelper = record helper for TTest
    function Test(aRecurse: Boolean): Integer;
  end;

function TTest.Test(aRecurse: Boolean): Integer;
begin
  Result := 1;
end;

function TTestHelper.Test(aRecurse: Boolean): Integer;
begin
  if aRecurse then
    Result := inherited Test(False)
  else
    Result := 2;
  end;
end;
```

## 10.4 Inheritance

As noted in the previous section, it is possible to create descendents of helper classes. Since only the last helper class in the current scope can be used, it is necessary to descend a helper class from another one if methods of both helpers must be used. More on this in a subsequent section.

A descendent of a class helper can extend a different class than its parent. The following is a valid class helper for `TMyObject`:

```
TObjectHelper = class helper for TObject
  procedure SomeMethod;
end;

TMyObject = class(TObject)
end;

TMyObjectHelper = class helper(TObjectHelper) for TMyObject
  procedure SomeOtherMethod;
end;
```

The `TMyObjectHelper` extends `TObjectHelper`, but does not extend the `TObject` class, it only extends the `TMyObject` class.

Since records know no inheritance, it is obvious that descendants of record helpers can only extend the same record.

**Remark:** For maximum delphi compatibility, it is impossible to create descendants of record helpers in Delphi mode.

## 10.5 Usage

Once a helper class is defined, its methods can be used whenever the helper class is in scope. This means that if it is defined in a separate unit, then this unit should be in the uses clause wherever the methods of the helper class are used.

Consider the following unit:

```
{ $mode objfpc }
{ $h+ }
unit oha;

interface

Type
  TObjectHelper = class helper for TObject
    function AsString(const aFormat: String): String;
  end;

implementation

uses sysutils;

function TObjectHelper.AsString(const aFormat: String): String;
begin
```

```
    Result := Format(aFormat, [ToString]);
end;

end.
```

Then the following will compile:

```
Program Example113;

uses oha;

{ Program to demonstrate the class helper scope. }

Var
    o : TObject;

begin
    O:=TObject.Create;
    Writeln(O.AsString('O as a string : %s'));
end.
```

But, if a second unit (ohb) is created:

```
{ $mode objfpc }
{ $h+ }
unit ohb;

interface

Type
    TObjectHelper = class helper for TObject
        function MemoryLocation: String;
    end;

implementation

uses sysutils;

function TObjectHelper.MemoryLocation: String;

begin
    Result := format('%p', [pointer(Self)]);
end;

end.
```

And is added after the first unit in the uses clause:

```
Program Example113;

uses oha, ohb;

{ Program to demonstrate the class helper scope. }
```

```
Var
  o : TObject;

begin
  O:=TObject.Create;
  Writeln(O.AsString('O as a string : %s'));
  Writeln(O.MemoryLocation);
end.
```

Then the compiler will complain that it does not know the method 'AsString'. This is because the compiler stops looking for class helpers as soon as the first class helper is encountered. Since the `ohb` unit comes last in the uses clause, the compiler will only use `TAObjectHelper` as the class helper.

The solution is to re-implement unit `ohb`:

```
{ $mode objfpc }
{ $h+ }
unit ohc;

interface

uses oha;

Type
  TAObjectHelper = class helper(TObjectHelper) for TObject
    function MemoryLocation: String;
  end;

implementation

uses sysutils;

function TAObjectHelper.MemoryLocation: String;

begin
  Result := format('%p', [pointer(Self)]);
end;

end.
```

And after replacing unit `ohb` with `ohc`, the example program will compile and function as expected.

Note that it is not enough to include a unit with a class helper once in a project; The unit must be included whenever the class helper is needed.

## Chapter 11

# Objective-Pascal Classes

### 11.1 Introduction

The preferred programming language to access Mac OS X system frameworks is Objective-C. In order to fully realize the potential offered by system interfaces written in that language, a variant of Object Pascal exists in the Free Pascal compiler that tries to offer the same functionality as Objective-C. This variant is called Objective-Pascal.

The compiler has mode switches to enable the use of these Objective-C-related constructs. There are 2 kinds of Objective-C language features, discerned by a version number: Objective-C 1.0 and Objective-C 2.0.

The Objective-C 1.0 language features can be enabled by adding a modeswitch to the source file:

```
{ $modeswitch objectivec1 }
```

or by using the `-MObjectivec1` command line switch of the compiler.

The Objective-C 2.0 language features can be enabled using a similar modeswitch:

```
{ $modeswitch objectivec2 }
```

or the command-line option `-MObjectivec2`.

The Objective-C 2.0 language features are a superset of the Objective-C 1.0 language features, and therefore the latter switch automatically implies the former. Programs using Objective-C 2.0 language features will only work on Mac OS X 10.5 and later.

The fact that objective-C features are enabled using mode switches rather than actual syntax modes, means they can be used in combination with every general syntax mode (fpc, objfpc, tp, delphi, macpas). Note that a `{ $Mode }` directive switch will reset the mode switches, so the `{ $modeswitch }` statement should be located after it.

### 11.2 Objective-Pascal class declarations

Objective-C or -Pascal classes are declared much as Object Pascal classes are declared, but they use the `objcclass` keyword:

---

**Objective C Class types**

```
    message 'addSubview:';
    procedure setAutoresizingMask(mask: NSUInteger);
        message 'setAutoresizingMask:';
    procedure setAutoresizesSubviews(flag: LongBool);
        message 'setAutoresizesSubviews:';
    procedure drawRect(dirtyRect: NSRect);
        message 'drawRect:';
end;
```

As can be seen, the class definition is not so different from an Object Pascal class definition; Only the message directive is more prominently present: each Objective-C or Objective-Pascal method must have a message name associated with it. In the above example, no external name was specified for the class definition, meaning that the Pascal identifier is used as the name for the Objective-C class. However, since Objective-C is not so strict in its naming conventions, sometimes an alias must be created for an Objective-C class name that doesn't obey the Pascal identifier rules.

The following example defines an Objective-C class which is implemented in Pascal:

```
MyView = objcclass(NSView)
public
    data : Integer;
    procedure customMessage(dirtyRect: NSRect);
        message 'customMessage';
    procedure drawRect(dirtyRect: NSRect); override;
end;
```

The absence of the external keyword tells the compiler that the methods must be implemented later in the source file: it will be treated much like a regular object pascal class. Note the presence of the `override` directive: in Objective-C, all methods are virtual. In Object Pascal, overriding a virtual method must be done through the `override` directive. This has been extended to Objective-C classes: it allows the compiler to verify the correctness of the definition.

Unless the class is implementing the method of a protocol (more about this in a subsequent section), one of `message` or `override` is expected: all methods are virtual, and either a new method is started (or re-introduced), or an existing is overridden. Only in the case of a method that is part of a protocol, the method can be defined without `message` or `override`.

Note that the Objective-C class declaration may or may not specify a parent class. In Object Pascal, omitting a parent class will automatically make the new class a descendant of `TObject`. In Objective-C, this is not the case: the new class will be a new root class. However, Objective-C does have a class which fulfills the function of generic root class: `NSObject`, which can be considered the equivalent of `TObject` in Object Pascal. It has other root classes, but in general, Objective-Pascal classes should descend from `NSObject`. If a new root class is constructed anyway, it must implement the `NSObjectProtocol` - just as the `NSObject` class itself does.

Finally, objective-Pascal classes can have properties, but these properties are only usable in Pascal code: the compiler currently does not export the properties in a way that makes them usable from Objective-C.

### 11.3 Formal declaration

Object Pascal has the concept of Forward declarations. Objective-C takes this concept a bit further: it allows to declare a class which is defined in another unit. This has been dubbed 'Formal declaration' in Objective-Pascal. Looking at the syntax diagram, the following is a valid declaration:

```
MyExternalClass = objcclass external;
```

This is a formal declaration. It tells the compiler that `MyExternalClass` is an Objective-C class type, but that there is no declaration of the class members. The type can be used in the remainder of the unit, but its use is restricted to storage allocation (in a field or method parameter definition) and assignment (much like a pointer).

As soon as the class definition is encountered, the compiler can enforce type compatibility.

The following unit uses a formal declaration:

```
unit ContainerClass;

{$mode objfpc}
{$modeswitch objectivecl}

interface

type
  MyItemClass = objcclass external;

  MyContainerClass = objcclass
    private
      item: MyItemClass;
    public
      function getItem: MyItemClass; message 'getItem';
    end;

implementation

function MyContainerClass.getItem: MyItemClass;
begin
  result:=item; // Assignment is OK.
end;

end.
```

A second unit can contain the actual class declaration:

```
unit ItemClass;

{$mode objfpc}
{$modeswitch objectivecl}

interface

type
  MyItemClass = objcclass(NSObject)
    private
      content : longint;
    public
      function initWithContent(c: longint): MyItemClass;
        message 'initWithContent: ';
      function getContent: longint;
        message 'getContent';
    end;
```

```
implementation

function MyItemClass.initWithContent(c: longint):
    MyItemClass;
begin
    content:=c;
    result:=self;
end;

function MyItemClass.getContent: longint;
begin
    result:=content;
end;

end.
```

If both units are used in a program, the compiler knows what the class is and can verify the correctness of some assignments:

```
Program test;

{$mode objfpc}
{$modeswitch objectivecl}

uses
    ItemClass, ContainerClass;

var
    c: MyContainerClass;
    l: longint;
begin
    c:=MyContainerClass.alloc.init;
    l:=c.getItem.getContent;
end.
```

## 11.4 Allocating and de-allocating Instances

The syntax diagram of Objective-C classes shows that the notion of constructor and destructor is not supported in Objective-C. New instances are created in a 2-step process:

1. Call the 'alloc' method (send an 'alloc' message): This is a class method of NSObject, and returns a pointer to memory for the new instance. The use of `alloc` is a convention in Objective-C.
2. Send an 'initXXX' message. By convention, all classes have one or more 'InitXXX' methods that initializes all fields in the instance. This method will return the final instance pointer, which may be `Nil`.

The following code demonstrates this:

```
var
    obj: NSObject;
begin
```

By convention, the `initXXX` method will return `Nil` if initialization of some fields failed, so it is imperative that the result of the function is tested.

## 11.5 Protocol definitions

- Protocol methods can be marked optional, i.e. the class implementing the protocol can decide not to implement these methods.
- Protocols can inherit from multiple other protocols.

The following diagram shows how to declare a protocol. It starts with the `objcprotocol` keyword:

126

```

type
  MyProtocol = objcprotocol
    // default is required
    procedure aRequiredMethod;
    message 'aRequiredMethod';
  optional
    procedure anOptionalMethodWithPara (para: longint);
    message 'anOptionalMethodWithPara: ';
    procedure anotherOptionalMethod;
    message 'anotherOptionalMethod';
  required
    function aSecondRequiredMethod: longint;
    message 'aSecondRequiredMethod';
end;

MyClassImplementingProtocol = objcclass (NSObject, MyProtocol)
  procedure aRequiredMethod;
  procedure anOptionalMethodWithPara (para: longint);
  function aSecondRequiredMethod: longint;
end;

```

Note that in the class declaration, the message specifier was omitted. The compiler (and runtime) can deduce it from the protocol definition.

## 11.6 Categories

Similar to class helpers in Object Pascal, Objective-C has Categories. Categories allow to extend classes without actually creating a descendant of these classes. However, Objective-C categories provide more functionality than a class helper:

1. In Object Pascal, only 1 helper class can be in scope (the last one). In Objective-C, multiple categories can be in scope at the same time for a particular class.
2. In Object Pascal, a helper method cannot change an existing method present in the original class (but it can hide a method). In Objective-C, a category can also replace existing methods in another class rather than only add new ones. Since all methods are virtual in Objective-C, this also means that this method changes for all classes that inherit from the class in which the method was replaced (unless they override it).
3. Object Pascal helpers cannot be used to add interfaces to existing classes. By contrast, an Objective-C category can also implement protocols.

The definition of an objective-C class closely resembles a protocol definition, and is started with the `objccategory` keyword:

Note again the possibility of an alias for externally defined categories: objective-C 2.0 allows an empty category name. Note that the `reintroduce` modifier must be used if an existing method is being replaced rather than that a new method is being added.

When replacing a method, calling 'inherited' will not call the original method of the class, but instead will call the parent class' implementation of the method.

The following is an example of a category definition:

```
MyProtocol = objcprotocol
  procedure protocolmethod; message 'protocolmethod';
end;

MyCategory = objccategory(NSObject, MyProtocol)
  function hash: cuint; reintroduce;
  procedure protocolmethod; // from MyProtocol.
  class procedure newmethod; message 'newmethod';
end;
```

Note that this declaration replaces the `Hash` method of every class that descends from `NSObject` (unless it specifically overrides it).

## 11.7 Name scope and Identifiers

In Object Pascal, each identifier must be unique in its namespace: the unit. In Objective-C, this need not be the case and each type identifier must be unique among its kind: classes, protocols, categories, fields or methods. This is shown in the definitions of the basic protocol and class of Objective-C: Both protocol and class are called `NSObject`.

When importing Objective-C classes and protocols, the Objective-Pascal names of these types must conform to the Object Pascal rules, and therefore must have distinct names. Likewise, names that are valid identifiers in Objective-C may be reserved words in Object Pascal. They also must be renamed when imported.

To make this possible, the `External` and 'message' modifiers allow to specify a name: this is the name of the type or method as it exists in Objective-C:

```
NSObjectProtocol = objcprotocol external name 'NSObject'
  function _class: pobjc_class; message name 'class';
end;

NSObject = objcclass external (NSObjectProtocol)
  function _class: pobjc_class;
  class function classClass: pobjc_class; message 'class';
end;
```

## 11.8 Selectors

A Selector in Objective-C can be seen as an equivalent to a procedural type in Object Pascal.

In difference with the procedural type, Objective-C has only 1 selector type: `SEL`. It is defined in the `objc` unit - which is automatically included in the `uses` clause of any unit compiled with the `objectivecl` modeswitch.

To assign a value to a variable of type `SEL`, the `objcselector` method must be used:

```
{ $modeswitch objectivecl }
var
  a: SEL;
begin
  a:=objcselector('initWithWidth:andHeight:');
  a:=objcselector('myMethod');
end.
```

The `objc` unit contains methods to manipulate and use the selector.

## 11.9 The `id` type

The `id` type is special in Objective-C/Pascal. It is much like the pointer type in Object Pascal, except that it is a real class. It is assignment-compatible with instances of every `objcclass` and `objcprotocol` type, in two directions:

1. variables of any `objcclass`/`objcprotocol` type can be assigned to a variable of the type `id`.
2. variables of type `id` can be assigned to variables of any particular `objcclass`/`objcprotocol` type.

No explicit typecast is required for either of these assignments.

Additionally, any Objective-C method declared in an `objcclass` or `objccategory` that is in scope can be called when using an `id`-typed variable.

If, at run time, the actual `objcclass` instance stored in the `id`-typed variable does not respond to the sent message, the program will terminate with a run time error: much like the dispatch mechanism for variants under MS-Windows.

When there are multiple methods with the same Pascal identifier, the compiler will use the standard overload resolution logic to pick the most appropriate method. In this process, it will behave as if all `objcclass`/`objccategory` methods in scope have been declared as global procedures/functions with the `overload` specifier. Likewise, the compiler will print an error if it cannot determine which overloaded method to call.

In such cases, a list of all methods that could be used to implement the call will be printed as a hint.

To resolve the error, an explicit type cast must be used to tell the compiler which `objcclass` type contains the needed method.

## 11.10 Enumeration in Objective-C classes

Fast enumeration in Objective-C is a construct which allows to enumerate the elements in a Cocoa container class in a generic way. It is implemented using a `for-in` loop in Objective-C.

This has been translated to Objective-Pascal using the existing `for-in` loop mechanism. Therefore, the feature behaves identically in both languages. Note that it requires the Objective-C 2.0 mode switch to be activated.

The following is an example of the use of `for-in`:

```
{ $mode delphi }
{ $modeswitch objectivec2 }

uses
    CocoaAll;

var
    arr: NSMutableArray;
    element: NSString;
    pool: NSAutoreleasePool;
    i: longint;
begin
    pool:=NSAutoreleasePool.alloc.init;
    arr:=NSMutableArray.arrayWithObjects(
        NSSTR('One'),
        NSSTR('Two'),
        NSSTR('Three'),
        NSSTR('Four'),
        NSSTR('Five'),
        NSSTR('Six'),
        NSSTR('Seven'),
        nil);

    i:=0;
    for element in arr do
        begin
            inc(i);
            if i=2 then
                continue;
            if i=5 then
                break;
            if i in [2,5..10] then
                halt(1);
            NSLog(NSSTR('element: %@'),element);
        end;
    pool.release;
end.
```

## Chapter 12

# Expressions

Expressions occur in assignments or in tests. Expressions produce a value of a certain type. Expressions are built with two components: operators and their operands. Usually an operator is binary, i.e. it requires 2 operands. Binary operators occur always between the operands (as in  $X/Y$ ). Sometimes an operator is unary, i.e. it requires only one argument. A unary operator occurs always before the operand, as in  $-X$ .

When using multiple operands in an expression, the precedence rules of table (12.1) are used.

Table 12.1: Precedence of operators

Operator	Precedence	Category
Not, @	Highest (first)	Unary operators
* / div mod and shl shr as << >>	Second	Multiplying operators
+ - or xor	Third	Adding operators
= <> < > <= >= in is	Lowest (Last)	relational operators

When determining the precedence, the compiler uses the following rules:

1. In operations with unequal precedences the operands belong to the operator with the highest precedence. For example, in  $5*3+7$ , the multiplication is higher in precedence than the addition, so it is executed first. The result would be 22.
2. If parentheses are used in an expression, their contents is evaluated first. Thus,  $5*(3+7)$  would result in 50.

**Remark:** The order in which expressions of the same precedence are evaluated is not guaranteed to be left-to-right. In general, no assumptions on which expression is evaluated first should be made in such a case. The compiler will decide which expression to evaluate first based on optimization rules. Thus, in the following expression:

```
a := g(3) + f(2);
```

$f(2)$  may be executed before  $g(3)$ . This behaviour is distinctly different from Delphi or Turbo Pascal.

If one expression *must* be executed before the other, it is necessary to split up the statement using temporary results:

```
e1 := g(3);
a  := e1 + f(2);
```

**Remark:** The exponentiation operator (\*\*) is available for overloading, but is not defined on any of the standard Pascal types (floats and/or integers).

## 12.1 Expression syntax

An expression applies relational operators to simple expressions. Simple expressions are a series of terms (what a term is, is explained below), joined by adding operators.

The following are valid expressions:

```
GraphResult<>grError
(DoItToday=Yes) and (DoItTomorrow=No);
Day in Weekend
```

And here are some simple expressions:

```
A + B
-Pi
ToBe or NotToBe
```

Terms consist of factors, connected by multiplication operators.

Here are some valid terms:

```

2 * Pi
A Div B
(DoItToday=Yes) and (DoItTomorrow=No) ;
  
```

Factors are all other constructions:

## 12.2 Function calls

Function calls are part of expressions (although, using extended syntax, they can be statements too). They are constructed as follows:

The variable reference must be a procedural type variable reference. A method designator can only be used inside the method of an object. A qualified method designator can be used outside object methods too. The function that will get called is the function with a declared parameter list that matches the actual parameter list. This means that

1. The number of actual parameters must equal the number of declared parameters (unless default parameter values are used).
2. The types of the parameters must be compatible. For variable reference parameters, the parameter types must be exactly the same.

If no matching function is found, then the compiler will generate an error. Which error depends - among other things - on whether the function is overloaded or not: i.e. multiple functions with the same name, but different parameter lists.

There are cases when the compiler will not execute the function call in an expression. This is the case when assigning a value to a procedural type variable, as in the following example in Delphi or Turbo Pascal mode:

```
Type
  FuncType = Function: Integer;
Var A : Integer;
Function AddOne : Integer;
begin
  A := A+1;
  AddOne := A;
end;
Var F : FuncType;
    N : Integer;
begin
  A := 0;
  F := AddOne; { Assign AddOne to F, Don't call AddOne}
  N := AddOne; { N := 1 !!}
end.
```

In the above listing, the assignment to F will not cause the function AddOne to be called. The assignment to N, however, will call AddOne.

Sometimes, the call is desired, for instance in recursion in that case, the call must be forced. This can be done by adding the parenthesis to the function name:

```
function rd : char;

var
  c : char;

begin
  read(c);
  if (c='\') then
    c:=rd();
  rd:=c;
end;

var ch : char;
```

```
[today,tomorrow]
[Monday..Friday,Sunday]
[ 2, 3*2, 6*2, 9*2 ]
['A'..'Z','a'..'z','0'..'9']
```

**Remark:** If the first range specifier has a bigger ordinal value than the second, the resulting set will be empty, e.g., `['Z'..'A']` denotes an empty set. One should be careful when denoting a range.

## 12.4 Value typecasts

Sometimes it is necessary to change the type of an expression, or a part of the expression, to be able to be assignment compatible. This is done through a value typecast. The syntax diagram for a value typecast is as follows:

Value typecasts cannot be used on the left side of assignments, as variable typecasts. Here are some valid typecasts:

```
Byte('A')
Char(48)
boolean(1)
longint(@Buffer)
```

In general, the type size of the expression and the size of the type cast must be the same. However, for ordinal types (byte, char, word, boolean, enumerates) this is not so, they can be used interchangeably. That is, the following will work, although the sizes do not match.

```
Integer('A');
Char(4875);
boolean(100);
Word(@Buffer);
```

This is compatible with Delphi or Turbo Pascal behaviour.

## 12.5 Variable typecasts

A variable can be considered a single factor in an expression. It can therefore be typecast as well. A variable can be typecast to any type, provided the type has the same size as the original variable.

It is a bad idea to typecast integer types to real types and vice versa. It's better to rely on type assignment compatibility and using some of the standard type changing functions.

Note that variable typecasts can occur on either side of an assignment, i.e. the following are both valid typecasts:

```
Var
```

```
C : Char;  
B : Byte;  
  
begin  
  B:=Byte(C);  
  Char(B):=C;  
end;
```

Pointer variables can be typecasted to procedural types, but not to method pointers.

A typecast is an expression of the given type, which means the typecast can be followed by a qualifier:

```
Type  
  TWordRec = Packed Record  
    L,H : Byte;  
  end;  
  
Var  
  P : Pointer;  
  W : Word;  
  S : String;  
  
begin  
  TWordRec(W).L:=$FF;  
  TWordRec(W).H:=0;  
  S:=TObject(P).ClassName;
```

## 12.6 Unaligned typecasts

A special typecast is the `Unaligned` typecast of a variable or expression. This is not a real typecast, but is rather a hint for the compiler that the expression may be misaligned (i.e. not on an aligned memory address). Some processors do not allow direct access to misaligned data structures, and therefor must access the data byte per byte.

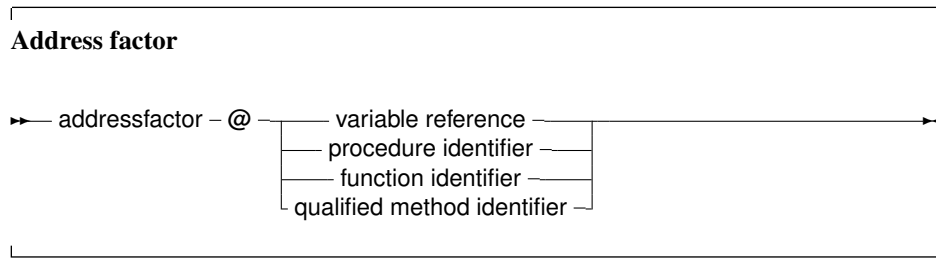

Typecasting an expression with the `unaligned` keyword signals the compiler that it should access the data byte per byte.

Example:

```
program me;  
  
Var  
  A : packed Array[1..20] of Byte;  
  I : LongInt;  
  
begin  
  For I:=1 to 20 do  
    A[I]:=I;  
    I:=PInteger(Unaligned(@A[13]))^;  
  end.
```

## 12.7 The @ operator

The address operator `@` returns the address of a variable, procedure or function. It is used as follows:

The @ operator returns a typed pointer if the \$T switch is on. If the \$T switch is off then the address operator returns an untyped pointer, which is assignment compatible with all pointer types. The type of the pointer is ^T, where T is the type of the variable reference. For example, the following will compile

```

Program tcast;
{$T-} { @ returns untyped pointer }

Type art = Array[1..100] of byte;
Var Buffer : longint;
    PLargeBuffer : ^art;

begin
    PLargeBuffer := @Buffer;
end.

```

Changing the {\$T-} to {\$T+} will prevent the compiler from compiling this. It will give a type mismatch error.

By default, the address operator returns an untyped pointer: applying the address operator to a function, method, or procedure identifier will give a pointer to the entry point of that function. The result is an untyped pointer.

This means that the following will work:

```

Procedure MyProc;

begin
end;

Var
    P : PChar;

begin
    P:=@MyProc;
end;

```

By default, the address operator must be used if a value must be assigned to a procedural type variable. This behaviour can be avoided by using the -Mtp or -MDelphi switches, which result in a more compatible Delphi or Turbo Pascal syntax.

## 12.8 Operators

Operators can be classified according to the type of expression they operate on. We will discuss them type by type.

### 12.8.1 Arithmetic operators

Arithmetic operators occur in arithmetic operations, i.e. in expressions that contain integers or reals. There are 2 kinds of operators : Binary and unary arithmetic operators. Binary operators are listed in table (12.2), unary operators are listed in table (12.3).

Table 12.2: Binary arithmetic operators

Operator	Operation
+	Addition
-	Subtraction
*	Multiplication
/	Division
Div	Integer division
Mod	Remainder

With the exception of `Div` and `Mod`, which accept only integer expressions as operands, all operators accept real and integer expressions as operands.

For binary operators, the result type will be integer if both operands are integer type expressions. If one of the operands is a real type expression, then the result is real.

As an exception, division (`/`) results always in real values.

Table 12.3: Unary arithmetic operators

Operator	Operation
+	Sign identity
-	Sign inversion

For unary operators, the result type is always equal to the expression type. The division (`/`) and `Mod` operator will cause run-time errors if the second argument is zero.

The sign of the result of a `Mod` operator is the same as the sign of the left side operand of the `Mod` operator. In fact, the `Mod` operator is equivalent to the following operation :

$$I \text{ mod } J = I - (I \text{ div } J) * J$$

But it executes faster than the right hand side expression.

### 12.8.2 Logical operators

Logical operators act on the individual bits of ordinal expressions. Logical operators require operands that are of an integer type, and produce an integer type result. The possible logical operators are listed in table (12.4).

Table 12.4: Logical operators

Operator	Operation
<code>not</code>	Bitwise negation (unary)
<code>and</code>	Bitwise and
<code>or</code>	Bitwise or
<code>xor</code>	Bitwise xor
<code>shl</code>	Bitwise shift to the left
<code>shr</code>	Bitwise shift to the right
<code>&lt;&lt;</code>	Bitwise shift to the left (same as <code>shl</code> )
<code>&gt;&gt;</code>	Bitwise shift to the right (same as <code>shr</code> )

The following are valid logical expressions:

```
A shr 1 { same as A div 2, but faster}
Not 1   { equals -2 }
Not 0   { equals -1 }
Not -1  { equals 0  }
B shl 2 { same as B * 4 for integers }
1 or 2  { equals 3  }
3 xor 1 { equals 2  }
```

### 12.8.3 Boolean operators

Boolean operators can be considered as logical operations on a type with 1 bit size. Therefore the `shl` and `shr` operations have little sense. Boolean operators can only have boolean type operands, and the resulting type is always boolean. The possible operators are listed in table (12.5)

Table 12.5: Boolean operators

Operator	Operation
<code>not</code>	logical negation (unary)
<code>and</code>	logical and
<code>or</code>	logical or
<code>xor</code>	logical xor

**Remark:** By default, boolean expressions are evaluated with short-circuit evaluation. This means that from the moment the result of the complete expression is known, evaluation is stopped and the result is returned. For instance, in the following expression:

```
B := True or MaybeTrue;
```

The compiler will never look at the value of `MaybeTrue`, since it is obvious that the expression will always be `True`. As a result of this strategy, if `MaybeTrue` is a function, it will not get called ! (This can have surprising effects when used in conjunction with properties)

### 12.8.4 String operators

There is only one string operator: `+`. Its action is to concatenate the contents of the two strings (or characters) it acts on. One cannot use `+` to concatenate null-terminated (`PChar`) strings. The

following are valid string operations:

```
'This is ' + 'VERY ' + 'easy !'
Dirname+'\''
```

The following is not:

```
Var
  Dirname : PChar;
...
  Dirname := Dirname+'\'';
```

Because `Dirname` is a null-terminated string.

Note that if all strings in a string expressions are short strings, the resulting string is also a short string. Thus, a truncation may occur: there is no automatic upscaling to ansistring.

If all strings in a string expression are ansistrings, then the result is an ansistring.

If the expression contains a mix of ansistrings and shortstrings, the result is an ansistring.

The value of the `{ $H }` switch can be used to control the type of constant strings; by default, they are short strings (and thus limited to 255 characters).

### 12.8.5 Set operators

The following operations on sets can be performed with operators: union, difference, symmetric difference, inclusion and intersection. Elements can be added or removed from the set with the `Include` or `Exclude` operators. The operators needed for this are listed in table (12.6).

Table 12.6: Set operators

Operator	Action
+	Union
-	Difference
*	Intersection
><	Symmetric difference
<=	Contains
include	include an element in the set
exclude	exclude an element from the set
in	check wether an element is in a set

The set type of the operands must be the same, or an error will be generated by the compiler.

The following program gives some valid examples of set operations:

```
Type
  Day = (mon,tue,wed,thu,fri,sat,sun);
  Days = set of Day;

Procedure PrintDays(W : Days);
Const
  DayNames : array [Day] of String[3]
    = ('mon','tue','wed','thu',
       'fri','sat','sun');
```

```

Var
  D : Day;
  S : String;
begin
  S:='';
  For D:=Mon to Sun do
    if D in W then
      begin
        If (S<>'') then S:=S+', ';
        S:=S+DayNames[D];
      end;
  Writeln('[' , S, ']' );
end;

Var
  W : Days;

begin
  W:=[mon,tue]+[wed,thu,fri]; // equals [mon,tue,wed,thu,fri]
  PrintDays(W);
  W:=[mon,tue,wed]-[wed];      // equals [mon,tue]
  PrintDays(W);
  W:=[mon,tue,wed]-[wed,thu];  // also equals [mon,tue]
  PrintDays(W);
  W:=[mon,tue,wed]*[wed,thu,fri]; // equals [wed]
  PrintDays(W);
  W:=[mon,tue,wed]><[wed,thu,fri]; // equals [mon,tue,thu,fri]
  PrintDays(W);
end.

```

As can be seen, the union is equivalent to a binary OR, while the intersection is equivalent to a binary AND, and the summetric difference equals a XOR operation.

The Include and Exclude operations are equivalent to a union or a difference with a set of 1 element. Thus,

```
Include(W,wed);
```

is equivalent to

```
W:=W+[wed];
```

and

```
Exclude(W,wed);
```

is equivalent to

```
W:=W-[wed];
```

The In operation results in a True if the left operand (an element) is included of the right operand (a set), the result will be False otherwise.

## 12.8.6 Relational operators

The relational operators are listed in table (12.7)

Table 12.7: Relational operators

Operator	Action
=	Equal
<>	Not equal
<	Strictly less than
>	Strictly greater than
<=	Less than or equal
>=	Greater than or equal
in	Element of

Normally, left and right operands must be of the same type. There are some notable exceptions, where the compiler can handle mixed expressions:

1. Integer and real types can be mixed in relational expressions.
2. If the operator is overloaded, and an overloaded version exists whose arguments types match the types in the expression.
3. Short-, Ansi- and widestring types can be mixed.

Comparing strings is done on the basis of their character code representation.

When comparing pointers, the addresses to which they point are compared. This also is true for `PChar` type pointers. To compare the strings the `PChar` point to, the `StrComp` function from the `strings` unit must be used. The `in` returns `True` if the left operand (which must have the same ordinal type as the set type, and which must be in the range 0..255) is an element of the set which is the right operand, otherwise it returns `False`.

### 12.8.7 Class operators

Class operators are slightly different from the operators above in the sense that they can only be used in class expressions which return a class. There are only 2 class operators, as can be seen in table (12.8).

Table 12.8: Class operators

Operator	Action
is	Checks class type
as	Conditional typecast

An expression containing the `is` operator results in a boolean type. The `is` operator can only be used with a class reference or a class instance. The usage of this operator is as follows:

```
Object is Class
```

This expression is completely equivalent to

```
Object.InheritsFrom(Class)
```

If `Object` is `Nil`, `False` will be returned.

The following are examples:

```
Var
  A : TObject;
  B : TClass;

begin
  if A is TComponent then ;
  If A is B then;
end;
```

The `as` operator performs a conditional typecast. It results in an expression that has the type of the class:

```
Object as Class
```

This is equivalent to the following statements:

```
If Object=nil then
  Result:=Nil
else if Object is Class then
  Result:=Class(Object)
else
  Raise Exception.Create(SErrInvalidTypeCast);
```

Note that if the object is `nil`, the `as` operator does not generate an exception.

The following are some examples of the use of the `as` operator:

```
Var
  C : TComponent;
  O : TObject;

begin
  (C as TEdit).Text:='Some text';
  C:=O as TComponent;
end;
```

The `as` and `is` operators also work on COM interfaces. They can be used to check whether an interface also implements another interface as in the following example:

```
{ $mode objfpc }

uses
  SysUtils;

type
  IMyInterface1 = interface
    ['{DD70E7BB-51E8-45C3-8CE8-5F5188E19255}']
    procedure Bar;
  end;

  IMyInterface2 = interface
    ['{7E5B86C4-4BC5-40E6-A0DF-D27DBF77BCA0}']
    procedure Foo;
  end;
```

```
TMyObject = class(TInterfacedObject, IMyInterfacel, IMyInterface2)
    procedure Bar;
    procedure Foo;
end;

procedure TMyObject.Bar;
begin

end;

procedure TMyObject.Foo;
begin

end;

var
    i: IMyInterfacel;
begin
    i := TMyObject.Create;
    i.Bar;
    Writeln(BoolToStr(i is IMyInterface2, True)); // prints true
    Writeln(BoolToStr(i is IDispatch, True)); // prints false
    (i as IMyInterface2).Foo;
end.
```

Additionally, the `is` operator can be used to check if a class implements an interface, and the `varas` operator can be used to typecast an interface back to the class:

```
{ $mode objfpc }
var
    i: IMyInterface;
begin
    i := TMyObject.Create;
    Writeln(BoolToStr(i is TMyObject, True)); // prints true
    Writeln(BoolToStr(i is TObject, True)); // prints true
    Writeln(BoolToStr(i is TAggregatedObject, True)); // prints false
    (i as TMyObject).Foo;
end.
```

Although the interfaces must be COM interfaces, the typecast back to a class will only work if the interface comes from an Object Pascal class. It will not work on interfaces obtained from the system by COM.

# Chapter 13

## Statements

The heart of each algorithm are the actions it takes. These actions are contained in the statements of a program or unit. Each statement can be labeled and jumped to (within certain limits) with `Goto` statements. This can be seen in the following syntax diagram:

A label can be an identifier or an integer digit.

### 13.1 Simple statements

A simple statement cannot be decomposed in separate statements. There are basically 4 kinds of simple statements:

Of these statements, the *raise statement* will be explained in the chapter on Exceptions (chapter [17](#), page [203](#))

#### 13.1.1 Assignments

Assignments give a value to a variable, replacing any previous value the variable might have had:

In addition to the standard Pascal assignment operator (`:=`), which simply replaces the value of the variable with the value resulting from the expression on the right of the `:=` operator, Free Pascal supports some C-style constructions. All available constructs are listed in table (13.1).

Table 13.1: Allowed C constructs in Free Pascal

Assignment	Result
<code>a += b</code>	Adds <code>b</code> to <code>a</code> , and stores the result in <code>a</code> .
<code>a -= b</code>	Subtracts <code>b</code> from <code>a</code> , and stores the result in <code>a</code> .
<code>a *= b</code>	Multiplies <code>a</code> with <code>b</code> , and stores the result in <code>a</code> .
<code>a /= b</code>	Divides <code>a</code> through <code>b</code> , and stores the result in <code>a</code> .

For these constructs to work, the `-Sc` command-line switch must be specified.

**Remark:** These constructions are just for typing convenience, they don't generate different code. Here are some examples of valid assignment statements:

```

X := X+Y;
X+=Y;      { Same as X := X+Y, needs -Sc command line switch}
X/=2;      { Same as X := X/2, needs -Sc command line switch}
Done := False;
Weather := Good;
MyPi := 4* Tan(1);

```

Keeping in mind that the dereferencing of a typed pointer results in a variable of the type the pointer points to, the following are also valid assignments:

```

Var
  L : ^Longint;
  P : PPChar;

begin
  L^:=3;
  P^^:='A';

```

Note the double dereferencing in the second assignment.

### 13.1.2 Procedure statements

Procedure statements are calls to subroutines. There are different possibilities for procedure calls:

- A normal procedure call.

- An object method call (fully qualified or not).
- Or even a call to a procedural type variable.

All types are present in the following diagram:

The Free Pascal compiler will look for a procedure with the same name as given in the procedure statement, and with a declared parameter list that matches the actual parameter list. The following are valid procedure statements:

```
Usage;
WriteLn('Pascal is an easy language !');
Doit();
```

**Remark:** When looking for a function that matches the parameter list of the call, the parameter types should be assignment-compatible for value and const parameters, and should match exactly for parameters that are passed by reference.

### 13.1.3 Goto statements

Free Pascal supports the `goto` jump statement. Its prototype syntax is

When using `goto` statements, the following must be kept in mind:

1. The jump label must be defined in the same block as the `Goto` statement.
2. Jumping from outside a loop to the inside of a loop or vice versa can have strange effects.
3. To be able to use the `Goto` statement, the `-Sg` compiler switch must be used, or `{ $GOTO ON }` must be used.

**Remark:** In iso or macpas mode, or with the modeswitch "nonlocalgoto", the compiler will also allow non-local gotos.

`Goto` statements are considered bad practice and should be avoided as much as possible. It is always possible to replace a `goto` statement by a construction that doesn't need a `goto`, although this construction may not be as clear as a `goto` statement. For instance, the following is an allowed `goto` statement:

```

label
  jump to;
...
Jump to :
  Statement;
...
Goto jump to;
...

```

## 13.2 Structured statements

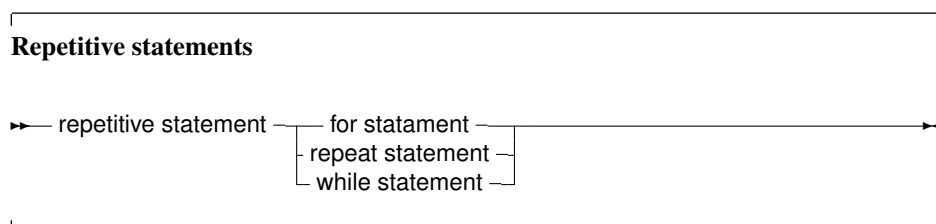

Structured statements can be broken into smaller simple statements, which should be executed repeatedly, conditionally or sequentially:

Conditional statements come in 2 flavours :

Repetitive statements come in 3 flavours:

The following sections deal with each of these statements.

### 13.2.1 Compound statements

Compound statements are a group of statements, separated by semicolons, that are surrounded by the keywords `Begin` and `End`. The last statement - before the `End` keyword - doesn't need to be followed by a semicolon, although it is allowed. A compound statement is a way of grouping statements together, executing the statements sequentially. They are treated as one statement in cases where Pascal syntax expects 1 statement, such as in `if...then...else` statements.

### Compound statements

→ compound statement – **begin** – statement – **end** →  
 ;

## 13.2.2 The Case statement

Free Pascal supports the `case` statement. Its syntax diagram is

### Case statement

→ case statement – **case** – expression – **of** – case – **end** →  
 ; else part ;

→ case – constant – .. – constant – : – statement →  
 ,

→ else part – **else** – statementlist →  
**otherwise**

The constants appearing in the various case parts must be known at compile-time, and can be of the following types : enumeration types, Ordinal types (except boolean), and chars or string types. The case expression must be also of this type, or a compiler error will occur. All case constants must have the same type.

The compiler will evaluate the case expression. If one of the case constants' value matches the value of the expression, the statement that follows this constant is executed. After that, the program continues after the final `end`.

If none of the case constants match the expression value, the statement list after the `else` or `otherwise` keyword is executed. This can be an empty statement list. If no else part is present, and no case constant matches the expression value, program flow continues after the final `end`.

The case statements can be compound statements (i.e. a `Begin..End` block).

**Remark:** Contrary to Turbo Pascal, duplicate case labels are not allowed in Free Pascal, so the following code will generate an error when compiling:

```
Var i : integer;
...
Case i of
  3 : DoSomething;
  1..5 : DoSomethingElse;
end;
```

The compiler will generate a `Duplicate case label` error when compiling this, because the 3 also appears (implicitly) in the range 1..5. This is similar to Delphi syntax.

The following are valid case statements:

```
Case C of
  'a' : WriteLn ('A pressed');
  'b' : WriteLn ('B pressed');
  'c' : WriteLn ('C pressed');
else
  WriteLn ('unknown letter pressed : ',C);
end;

Or

Case C of
  'a','e','i','o','u' : WriteLn ('vowel pressed');
  'y' : WriteLn ('This one depends on the language');
else
  WriteLn ('Consonant pressed');
end;

Case Number of
  1..10 : WriteLn ('Small number');
  11..100 : WriteLn ('Normal, medium number');
else
  WriteLn ('HUGE number');
end;
```

Free Pascal allows the use of strings as case labels, and in that case the case variable must also be a string. When using string types, the case variable and the various labels are compared in a case-sensitive way.

```
Case lowercase(OS) of
  'windows',
  'dos' : WriteLn ('Microsoft playtform');
  'macos',
  'darwin' : WriteLn('Apple platform');
  'linux',
  'freebsd',
  'netbsd' : WriteLn('Community platform');
else
  WriteLn ('Other platform');
end;
```

The case with strings is equivalent to a series of `if then else` statements, no optimizations are performed.

However, ranges are allowed, and are the equivalent of an

```
if (value>=beginrange) and (value<=endrange) then
  begin
  end;
```

### 13.2.3 The `if .. then .. else` statement

The `if .. then .. else..` prototype syntax is

---

**If then statements**

If the expression evaluates to `False`, then the statement following the `else` keyword is executed, if it is present.

because the loop variable `I` cannot be assigned to inside the loop.

If the statement is a compound statement, then the `Break` and `Continue` system routines can be used to jump to the end or just after the end of the `For` statement. Note that `Break` and `Continue` are not reserved words and therefor can be overloaded.

### 13.2.5 The `For . . in . . do` statement

As of version 2.4.2, Free Pascal supports the `For . . in` loop construction. A `for . . in` loop is used in case one wants to calculate something a fixed number of times with an enumerable loop variable. The prototype syntax is as follows:

Here, `Statement` can be a compound statement. The enumerable must be an expression that consists of a fixed number of elements: the loop variable will be made equal to each of the elements in turn and the statement following the `do` keyword will be executed.

The enumerable expression can be one of 5 cases:

1. An enumeration type identifier. The loop will then be over all elements of the enumeration type. The control variable must be of the enumeration type.
2. A set value. The loop will then be over all elements in the set, the control variable must be of the base type of the set.
3. An array value. The loop will be over all elements in the array, and the control variable must have the same type as an element in the array. As a special case, a string is regarded as an array of characters.
4. An enumerable class instance. This is an instance of a class that supports the `IEnumerator` and `IEnumerable` interfaces. In this case, the control variable's type must equal the type of the `IEnumerator.GetCurrent` return value.
5. Any type for which an `enumerator` operator is defined. The `enumerator` operator must return a class that implements the `IEnumerator` interface. The type of the control variable's type must equal the type of the `enumerator` class `GetCurrent` return value type.

The simplest case of the `for . . in` loop is using an enumerated type:

```

Type
  TWeekday = (monday, tuesday, wednesday, thursday,
              friday, saturday, sunday);

Var
  d : TWeekday;
  
```

```
begin
  for d in TWeekday do
    writeln(d);
  end.
```

This will print all week days to the screen.

The above `for . . in` construct is equivalent to the following `for . . to` construct:

```
Type
  TWeekDay = (monday, tuesday, wednesday, thursday,
              friday, saturday, sunday);

Var
  d : TWeekday;

begin
  for d:=Low(TWeekday) to High(TWeekday) do
    writeln(d);
  end.
```

A second case of `for . . in` loop is when the enumerable expression is a set, and then the loop will be executed once for each element in the set:

```
Type
  TWeekDay = (monday, tuesday, wednesday, thursday,
              friday, saturday, sunday);

Var
  Week : set of TWeekDay
        = [monday, tuesday, wednesday, thursday, friday];
  d : TWeekday;

begin
  for d in Week do
    writeln(d);
  end.
```

This will print the names of the week days to the screen. Note that the variable `d` is of the same type as the base type of the set.

The above `for . . in` construct is equivalent to the following `for . . to` construct:

```
Type
  TWeekDay = (monday, tuesday, wednesday, thursday,
              friday, saturday, sunday);

Var
  Week : set of TWeekDay
        = [monday, tuesday, wednesday, thursday, friday];

  d : TWeekday;

begin
  for d:=Low(TWeekday) to High(TWeekday) do
```

```
    if d in Week then
        writeln(d);
end.
```

The third possibility for a `for..in` loop is when the enumerable expression is an array:

```
var
    a : Array[1..7] of string
    = ('monday', 'tuesday', 'wednesday', 'thursday',
       'friday', 'saturday', 'sunday');

Var
    S : String;

begin
    For s in a do
        Writeln(s);
    end.
```

This will also print all days in the week, and is equivalent to

```
var
    a : Array[1..7] of string
    = ('monday', 'tuesday', 'wednesday', 'thursday',
       'friday', 'saturday', 'sunday');

Var
    i : integer;

begin
    for i:=Low(a) to high(a) do
        Writeln(a[i]);
    end.
```

A string type is equivalent to an array of char, and therefor a string can be used in a `for..in` loop. The following will print all letters in the alphabet, each letter on a line:

```
Var
    c : char;

begin
    for c in 'abcdefghijklmnopqrstuvwxyz' do
        writeln(c);
    end.
```

The fourth possibility for a `for..in` loop is using classes. A class can implement the `IEnumerable` interface, which is defined as follows:

```
IEnumerable = interface(IInterface)
    function GetEnumerator: IEnumerator;
end;
```

The actual return type of the `GetEnumerator` must not necessarily be an `IEnumerator` interface, instead, it can be a class which implements the methods of `IEnumerator`:

```
IEnumerator = interface(IIInterface)
  function GetCurrent: TObject;
  function MoveNext: Boolean;
  procedure Reset;
  property Current: TObject read GetCurrent;
end;
```

The `Current` property and the `MoveNext` method must be present in the class returned by the `GetEnumerator` method. The actual type of the `Current` property need not be a `TObject`. When encountering a `for..in` loop with a class instance as the 'in' operand, the compiler will check each of the following conditions:

- Whether the class in the enumerable expression implements a method `GetEnumerator`
- Whether the result of `GetEnumerator` is a class with the following method:

```
Function MoveNext : Boolean
```

- Whether the result of `GetEnumerator` is a class with the following read-only property:

```
Property Current : AType;
```

The type of the property must match the type of the control variable of the `for..in` loop.

Neither the `IEnumerator` nor the `IEnumerable` interfaces must actually be declared by the enumerable class: the compiler will detect whether these interfaces are present using the above checks. The interfaces are only defined for Delphi compatibility and are not used internally. (it would also be impossible to enforce their correctness).

The **Classes** unit contains a number of classes that are enumerable:

**TFPList** Enumerates all pointers in the list.

**TList** Enumerates all pointers in the list.

**TCollection** Enumerates all items in the collection.

**TStringList** Enumerates all strings in the list.

**TComponent** Enumerates all child components owned by the component.

Thus, the following code will also print all days in the week:

```
{ $mode objfpc }
uses classes;

Var
  Days : TStrings;
  D : String;

begin
  Days:=TStringList.Create;
  try
    Days.Add('Monday');
    Days.Add('Tuesday');
    Days.Add('Wednesday');
```

```
    Days.Add(' Thursday' );
    Days.Add(' Friday' );
    Days.Add(' Saturday' );
    Days.Add(' Sunday' );
    For D in Days do
        Writeln(D);
    Finally
        Days.Free;
    end;
end.
```

**Note** that the compiler enforces type safety: declaring D as an integer will result in a compiler error:

```
testsl.pp(20,9) Error: Incompatible types: got "AnsiString" expected "LongInt"
```

The above code is equivalent to the following:

```
{ $mode objfpc }
uses classes;

Var
    Days : TStrings;
    D : String;
    E : TStringsEnumerator;

begin
    Days:=TStringList.Create;
    try
        Days.Add(' Monday' );
        Days.Add(' Tuesday' );
        Days.Add(' Wednesday' );
        Days.Add(' Thursday' );
        Days.Add(' Friday' );
        Days.Add(' Saturday' );
        Days.Add(' Sunday' );
        E:=Days.GetEnumerator;
        try
            While E.MoveNext do
                begin
                    D:=E.Current;
                    Writeln(D);
                end;
            Finally
                E.Free;
            end;
        Finally
            Days.Free;
        end;
    end.
end.
```

Both programs will output the same result.

The fifth and last possibility to use a `for..in` loop can be used to enumerate almost any type, using the `enumerator operator`. The `enumerator operator` must return a class that has the same signature as the `IEnumerator` approach above. The following code will define an enumerator for the `Integer` type:

Type

```
TEvenEnumerator = Class
  FCurrent : Integer;
  FMax : Integer;
  Function MoveNext : Boolean;
  Property Current : Integer Read FCurrent;
end;

Function TEvenEnumerator.MoveNext : Boolean;

begin
  FCurrent:=FCurrent+2;
  Result:=FCurrent<=FMax;
end;

operator enumerator(i : integer) : TEvenEnumerator;

begin
  Result:=TEvenEnumerator.Create;
  Result.FMax:=i;
end;

var
  I : Integer;
  m : Integer = 4;

begin
  For I in M do
    Writeln(i);
  end.
```

The loop will print all nonzero even numbers smaller or equal to the enumerable. (2 and 4 in the case of the example).

Care must be taken when defining enumerator operators: the compiler will find and use the first available enumerator operator for the enumerable expression. For classes this also means that the `GetEnumerator` method is not even considered. The following code will define an enumerator operator which extracts the object from a stringlist:

```
{ $mode objfpc }
uses classes;
```

Type

```
TDayObject = Class
  DayOfWeek : Integer;
  Constructor Create(ADayOfWeek : Integer);
end;

TObjectEnumerator = Class
  FList : TStrings;
  FIndex : Integer;
  Function GetCurrent : TDayObject;
  Function MoveNext: boolean;
```

```
    Property Current : TDayObject Read GetCurrent;
end;

Constructor TDayObject.Create(ADayOfWeek : Integer);

begin
    DayOfWeek:=ADayOfWeek;
end;

Function TObjectEnumerator.GetCurrent : TDayObject;
begin
    Result:=FList.Objects[FIndex] as TDayObject;
end;

Function TObjectEnumerator.MoveNext: boolean;

begin
    Inc(FIndex);
    Result:=(FIndex<FList.Count);
end;

operator enumerator (s : TStringList) : TObjectEnumerator;

begin
    Result:=TObjectEnumerator.Create;
    Result.FList:=s;
    Result.FIndex:=-1;
end;

Var
    Days : TStringList;
    D : String;
    O : TDayObject;

begin
    Days:=TStringList.Create;
    try
        Days.AddObject('Monday',TDayObject.Create(1));
        Days.AddObject('Tuesday',TDayObject.Create(2));
        Days.AddObject('Wednesday',TDayObject.Create(3));
        Days.AddObject('Thursday',TDayObject.Create(4));
        Days.AddObject('Friday',TDayObject.Create(5));
        Days.AddObject('Saturday',TDayObject.Create(6));
        Days.AddObject('Sunday',TDayObject.Create(7));
        For O in Days do
            Writeln(O.DayOfWeek);
        Finally
            Days.Free;
        end;
    end.
```

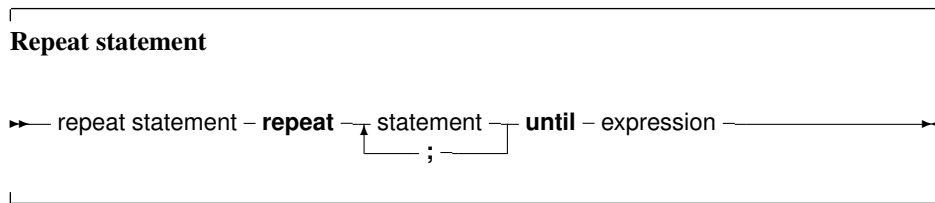

The above code will print the day of the week for each day in the week.

If a class is not enumerable, the compiler will report an error when it is encountered in a `for . . . in` loop.

**Remark:** Like the `for . . to` loop, it is not allowed to change (i.e. assign a value to) the value of a loop control variable inside the loop.

### 13.2.6 The Repeat...until statement

The `repeat` statement is used to execute a statement until a certain condition is reached. The statement will be executed at least once. The prototype syntax of the `Repeat . . until` statement is

This will execute the statements between `repeat` and `until` up to the moment when `Expression` evaluates to `True`. Since the `expression` is evaluated *after* the execution of the statements, they are executed at least once.

Be aware of the fact that the boolean expression `Expression` will be short-cut evaluated by default, meaning that the evaluation will be stopped at the point where the outcome is known with certainty.

The following are valid `repeat` statements

```
repeat
  WriteLn ('I =',i);
  I := I+2;
until I>100;
```

```
repeat
  X := X/2
until x<10e-3;
```

Note that the last statement before the `until` keyword does not need a terminating semicolon, but it is allowed.

The `Break` and `Continue` system routines can be used to jump to the end or just after the end of the `repeat . . . until` statement. Note that `Break` and `Continue` are not reserved words and therefor can be overloaded.

### 13.2.7 The `while...do` statement

A `while` statement is used to execute a statement as long as a certain condition holds. In difference with the `repeat` loop, this may imply that the statement is never executed.

The prototype syntax of the `While...do` statement is

This will execute `Statement` as long as `Expression` evaluates to `True`. Since `Expression` is evaluated *before* the execution of `Statement`, it is possible that `Statement` isn't executed at all. `Statement` can be a compound statement.

Be aware of the fact that the boolean expression `Expression` will be short-cut evaluated by default, meaning that the evaluation will be stopped at the point where the outcome is known with certainty.

The following are valid `while` statements:

```
I := I+2;
while i<=100 do
  begin
    WriteLn ('I =', i);
    I := I+2;
  end;
X := X/2;
while x>=10e-3 do
  X := X/2;
```

They correspond to the example loops for the `repeat` statements.

If the statement is a compound statement, then the `Break` and `Continue` reserved words can be used to jump to the end or just after the end of the `While` statement. Note that `Break` and `Continue` are not reserved words and therefor can be overloaded.

### 13.2.8 The `with` statement

The `with` statement serves to access the elements of a record or object or class, without having to specify the element's name each time. The syntax for a `with` statement is

#### With statement

→ with statement — variable reference — do — statement →

The variable reference must be a variable of a record, object or class type. In the `with` statement, any variable reference, or method reference is checked to see if it is a field or method of the record or object or class. If so, then that field is accessed, or that method is called. Given the declaration:

Type

```
Passenger = Record
  Name : String[30];
  Flight : String[10];
end;
```

Var

```
TheCustomer : Passenger;
```

The following statements are completely equivalent:

```
TheCustomer.Name := 'Michael';
TheCustomer.Flight := 'PS901';
```

and

```
With TheCustomer do
begin
  Name := 'Michael';
  Flight := 'PS901';
end;
```

The statement

```
With A,B,C,D do Statement;
```

is equivalent to

```
With A do
  With B do
    With C do
      With D do Statement;
```

This also is a clear example of the fact that the variables are tried *last to first*, i.e., when the compiler encounters a variable reference, it will first check if it is a field or method of the last variable. If not, then it will check the last-but-one, and so on. The following example shows this;

```
Program testw;
Type AR = record
  X,Y : Longint;
end;
PAR = ^Ar;

Var S,T : Ar;
begin
  S.X := 1;S.Y := 1;
  T.X := 2;T.Y := 2;
  With S,T do
    WriteLn (X, ' ', Y);
end.
```

The output of this program is

```
2 2
```

Showing thus that the X, Y in the WriteLn statement match the T record variable.

**Remark:** When using a With statement with a pointer, or a class, it is not permitted to change the pointer or the class in the With block. With the definitions of the previous example, the following illustrates what it is about:

```
Var p : PAR;

begin
  With P^ do
    begin
      // Do some operations
      P:=OtherP;
      X:=0.0;  // Wrong X will be used !!
    end;
```

The reason the pointer cannot be changed is that the address is stored by the compiler in a temporary register. Changing the pointer won't change the temporary address. The same is true for classes.

### 13.2.9 Exception Statements

Free Pascal supports exceptions. Exceptions provide a convenient way to program error and error-recovery mechanisms, and are closely related to classes. Exception support is explained in chapter 17, page 203

## 13.3 Assembler statements

An assembler statement allows to insert assembler code right in the Pascal code.

More information about assembler blocks can be found in the [Programmer's Guide](#). The register list is used to indicate the registers that are modified by an assembler statement in the assembler block. The compiler stores certain results in the registers. If the registers are modified in an assembler statement, the compiler should, sometimes, be told about it. The registers are denoted with their Intel names for the I386 processor, i.e., 'EAX', 'ESI' etc... As an example, consider the following assembler code:

```
asm
  Movl $1,%ebx
  Movl $0,%eax
  addl %eax,%ebx
end ['EAX','EBX'];
```

This will tell the compiler that it should save and restore the contents of the EAX and EBX registers when it encounters this asm statement.

Free Pascal supports various styles of assembler syntax. By default, AT&T syntax is assumed for the 80386 and compatibles platform. The default assembler style can be changed with the {`$asmmode xxx`} switch in the code, or the `-R` command-line option. More about this can be found in the [Programmer's Guide](#).

## Chapter 14

# Using functions and procedures

Free Pascal supports the use of functions and procedures. It supports

- Function overloading, i.e. functions with the same name but different parameter lists.
- `Const` parameters.
- Open arrays (i.e. arrays without bounds).
- Variable number of arguments as in C.
- Return-like construct as in C, through the `Exit` keyword.

**Remark:** In many of the subsequent paragraphs the words `procedure` and `function` will be used interchangeably. The statements made are valid for both, except when indicated otherwise.

### 14.1 Procedure declaration

A procedure declaration defines an identifier and associates it with a block of code. The procedure can then be called with a procedure statement.

See section 14.4, page 167 for the list of parameters. A procedure declaration that is followed by a block implements the action of the procedure in that block. The following is a valid procedure :

```

Procedure DoSomething (Para : String);
begin
  Writeln ('Got parameter : ', Para);
  Writeln ('Parameter in upper case : ', Upper(Para));
end;

```

Note that it is possible that a procedure calls itself.

## 14.2 Function declaration

A function declaration defines an identifier and associates it with a block of code. The block of code will return a result. The function can then be called inside an expression, or with a procedure statement, if extended syntax is on.

The result type of a function can be any previously declared type. contrary to Turbo Pascal, where only simple types could be returned.

## 14.3 Function results

The result of a function can be set by setting the result variable: this can be the function identifier or, (only in ObjFPC or Delphi mode) the special `Result` identifier:

```

Function MyFunction : Integer;

begin
  MyFunction:=12; // Return 12
end;

```

In Delphi or ObjFPC mode, the above can also be coded as:

```

Function MyFunction : Integer;

begin
  Result:=12;
end;

```

As an extension to Delphi syntax, the `ObjFPC` mode also supports a special extension of the `Exit` procedure:

```
Function MyFunction : Integer;

begin
    Exit(12);
end;
```

The `Exit` call sets the result of the function and jumps to the final `End` of the function declaration block. It can be seen as the equivalent of the `C return` instruction.

## 14.4 Parameter lists

When arguments must be passed to a function or procedure, these parameters must be declared in the formal parameter list of that function or procedure. The parameter list is a declaration of identifiers that can be referred to only in that procedure or function's block.

Constant parameters, out parameters and variable parameters can also be `untyped` parameters if they have no type identifier.

As of version 1.1, Free Pascal supports default values for both constant parameters and value parameters, but only for simple types. The compiler must be in `ObjFPC` or `DELPHI` mode to accept default values.

### 14.4.1 Value parameters

Value parameters are declared as follows:

When parameters are declared as value parameters, the procedure gets a *copy* of the parameters that the calling statement passes. Any modifications to these parameters are purely local to the procedure's block, and do not propagate back to the calling block.

A block that wishes to call a procedure with value parameters must pass assignment compatible parameters to the procedure. This means that the types should not match exactly, but can be converted to the actual parameter types. This conversion code is inserted by the compiler itself.

Care must be taken when using value parameters: value parameters makes heavy use of the stack, especially when using large parameters. The total size of all parameters in the formal parameter list should be below 32K for portability's sake (the Intel version limits this to 64K).

Open arrays can be passed as value parameters. See section 14.4.5, page 171 for more information on using open arrays.

For a parameter of a simple type (i.e. not a structured type), a default value can be specified. This can be an untyped constant. If the function call omits the parameter, the default value will be passed on to the function. For dynamic arrays or other types that can be considered as equivalent to a pointer, the only possible default value is `Nil`.

The following example will print 20 on the screen:

```
program testp;

Const
  MyConst = 20;

Procedure MyRealFunc(I : Integer = MyConst);

begin
  Writeln('Function received : ', I);
end;

begin
  MyRealFunc;
end.
```

## 14.4.2 Variable parameters

Variable parameters are declared as follows:

When parameters are declared as variable parameters, the procedure or function accesses immediately the variable that the calling block passed in its parameter list. The procedure gets a pointer to the variable that was passed, and uses this pointer to access the variable's value. From this, it follows that any changes made to the parameter, will propagate back to the calling block. This mechanism can be used to pass values back in procedures. Because of this, the calling block must pass a parameter of *exactly* the same type as the declared parameter's type. If it does not, the compiler will generate an error.

Open arrays can be passed as variable parameters. See section 14.4.5, page 171 for more information on using open arrays.

Note that default values are not supported for variable parameters. This would make little sense since it defeats the purpose of being able to pass a value back to the caller.

Out parameters (output parameters) are declared as follows:

If a variable must be used to pass a value to a function and retrieve data from the function, then a variable parameter must be used. If only a value must be retrieved, a `out` parameter can be used.

The difference of `out` parameters and parameters by reference is very small: the former gives the compiler more information about what happens to the arguments when passed to the procedure: it knows that the variable does not have to be initialized prior to the call. The following example illustrates this:

```
begin
    A:=2;
    Writeln('A is ',A);
end;
```

```
begin
  B:=2;
  Writeln('B is ',B);
end;
```

begin

```
DoA (C) ;
DoB (D) ;
end.
```

Both procedures `DoA` and `DoB` do practically the same. But `DoB`'s declaration gives more information to the compiler, allowing it to detect that `D` does not have to be initialized before `DoB` is called. Since the parameter `A` in `DoA` can receive a value as well as return one, the compiler notices that `C` was not initialized prior to the call to `DoA`:

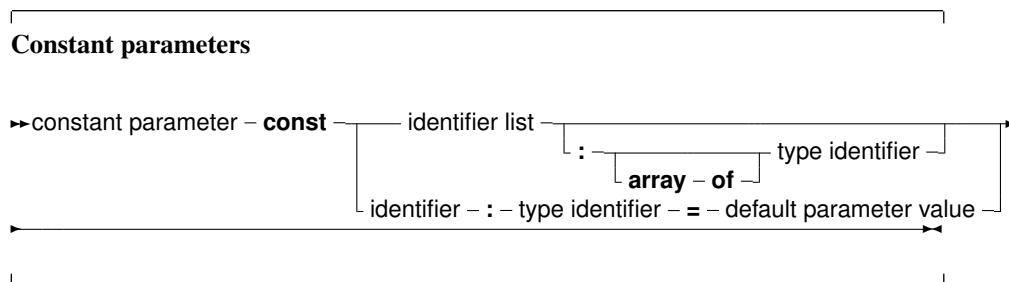

```
home: >fpc -S2 -vwhn testo.pp
testo.pp(19,8) Hint: Variable "C" does not seem to be initialized
```

This shows that it is better to use `out` parameters when the parameter is used only to return a value.

**Remark:** `Out` parameters are only supported in Delphi and ObjFPC mode. For the other modes, `out` is a valid identifier.

#### 14.4.4 Constant parameters

In addition to variable parameters and value parameters Free Pascal also supports Constant parameters. A constant parameter can be specified as follows:

Specifying a parameter as Constant is giving the compiler a hint that the contents of the parameter will not be changed by the called routine. This allows the compiler to perform optimizations which it could not do otherwise, and also to perform certain checks on the code inside the routine: namely, it can forbid assignments to the parameter. Furthermore a `const` parameter cannot be passed on to another function that requires a variable parameter: the compiler can check this as well. The main use for this is reducing the stack size, hence improving performance, and still retaining the semantics of passing by value...

**Remark:** Contrary to Delphi, no assumptions should be made about how `const` parameters are passed to the underlying routine. In particular, the assumption that parameters with large size are passed by reference is not correct. For this the `constref` parameter type should be used, which is available as of version 2.5.1 of the compiler.

An exception is the `stdcall` calling convention: for compatibility with COM standards, large `const` parameters are passed by reference.

**Remark:** Note that specifying `const` is a contract between the programmer and the compiler. It is the programmer who tells the compiler that the contents of the `const` parameter will not be changed when the routine is executed, it is *not* the compiler who tells the programmer that the parameter will not be changed.

This is particularly important and visible when using refcounted types. For such types, the (invisible) incrementing and decrementing of any reference count is omitted when `const` is used. Doing so often allows the compiler to omit invisible try/finally frames for these routines.

As a side effect, the following code will produce not the expected output:

```
Var
  S : String = 'Something';

Procedure DoIt (Const T : String);

begin
  S:='Something else';
  Writeln(T);
end;

begin
  DoIt (S);
end.
```

Will write

Something else

This behaviour is by design.

Constant parameters can also be untyped. See section [14.4.2](#), page [168](#) for more information about untyped parameters.

As for value parameters, constant parameters can get default values.

Open arrays can be passed as constant parameters. See section [14.4.5](#), page [171](#) for more information on using open arrays.

### 14.4.5 Open array parameters

Free Pascal supports the passing of open arrays, i.e. a procedure can be declared with an array of unspecified length as a parameter, as in Delphi. Open array parameters can be accessed in the procedure or function as an array that is declared with starting index 0, and last element index `High (parameter)`. For example, the parameter

```
Row : Array of Integer;
```

would be equivalent to

```
Row : Array[0..N-1] of Integer;
```

Where N would be the actual size of the array that is passed to the function. `N-1` can be calculated as `High (Row)`.

Specifically, if an empty array is passed, then `High (Parameter)` returns -1, while `low (Parameter)` returns 0.

Open parameters can be passed by value, by reference or as a constant parameter. In the latter cases the procedure receives a pointer to the actual array. In the former case, it receives a copy of the array. In a function or procedure, open arrays can only be passed to functions which are also declared with open arrays as parameters, *not* to functions or procedures which accept arrays of fixed length. The following is an example of a function using an open array:

```
Function Average (Row : Array of integer) : Real;
Var I : longint;
    Temp : Real;
begin
```

```

Temp := Row[0];
For I := 1 to High(Row) do
  Temp := Temp + Row[i];
Average := Temp / (High(Row)+1);
end;

```

As of FPC 2.2, it is also possible to pass partial arrays to a function that accepts an open array. This can be done by specifying the range of the array which should be passed to the open array.

Given the declaration

```

Var
  A : Array[1..100];

```

the following call will compute and print the average of the 100 numbers:

```

Writeln('Average of 100 numbers: ', Average(A));

```

But the following will compute and print the average of the first and second half:

```

Writeln('Average of first 50 numbers: ', Average(A[1..50]));
Writeln('Average of last 50 numbers: ', Average(A[51..100]));

```

### 14.4.6 Array of const

In Object Pascal or Delphi mode, Free Pascal supports the `Array of Const` construction to pass parameters to a subroutine.

This is a special case of the `Open array` construction, where it is allowed to pass any expression in an array to a function or procedure. The expression must have a simple result type: structures cannot be passed as an argument. This means that all ordinal, float or string types can be passed, as well as pointers, classes and interfaces.

The elements of the `array of const` are converted to a special variant record:

```

Type
  PVarRec = ^TVarRec;
  TVarRec = record
    case VType : PPrint of
      vtInteger      : (VInteger: Longint);
      vtBoolean      : (VBoolean: Boolean);
      vtChar          : (VChar: Char);
      vtWideChar      : (VWideChar: WideChar);
      vtExtended      : (VExtended: PExtended);
      vtString        : (VString: PShortString);
      vtPointer       : (VPointer: Pointer);
      vtPChar         : (VPChar: PChar);
      vtObject        : (VObject: TObject);
      vtClass         : (VClass: TClass);
      vtPWideChar     : (VPWideChar: PWideChar);
      vtAnsiString    : (VAnsiString: Pointer);
      vtCurrency      : (VCurrency: PCurrency);
      vtVariant       : (VVariant: PVariant);
      vtInterface     : (VInterface: Pointer);
      vtWideString    : (VWideString: Pointer);

```

```

        vtInt64      : (VInt64: PInt64);
        vtQWord     : (VQWord: PQWord);
    end;

```

Therefor, inside the procedure body, the array of `const` argument is equivalent to an open array of `TVarRec`:

```

Procedure Testit (Args: Array of const);

Var I : longint;

begin
    If High(Args)<0 then
        begin
            Writeln ('No aguments');
            exit;
        end;
    Writeln ('Got ',High(Args)+1,' arguments :');
    For i:=0 to High(Args) do
        begin
            write ('Argument ',i,' has type ');
            case Args[i].vtype of
                vtinteger      :
                    Writeln ('Integer, Value :',args[i].vinteger);
                vtboolean     :
                    Writeln ('Boolean, Value :',args[i].vboolean);
                vtchar        :
                    Writeln ('Char, value : ',args[i].vchar);
                vtextended    :
                    Writeln ('Extended, value : ',args[i].VExtended^);
                vtString      :
                    Writeln ('ShortString, value :',args[i].VString^);
                vtPointer     :
                    Writeln ('Pointer, value : ',Longint(Args[i].VPointer));
                vtPChar       :
                    Writeln ('PChar, value : ',Args[i].VPChar);
                vtObject      :
                    Writeln ('Object, name : ',Args[i].VObject.Classname);
                vtClass       :
                    Writeln ('Class reference, name :',Args[i].VClass.Classname);
                vtAnsiString  :
                    Writeln ('AnsiString, value :',AnsiString(Args[I].VAnsiString));
            else
                Writeln ('(Unknown) : ',args[i].vtype);
            end;
        end;
    end;
end;

```

In code, it is possible to pass an arbitrary array of elements to this procedure:

```

S:='AnsiString 1';
T:='AnsiString 2';
Testit ([]);
Testit ([1,2]);

```

```
Testit ([ 'A', 'B' ] );
Testit ([ TRUE, FALSE, TRUE ] );
Testit ([ 'String', 'Another string' ] );
Testit ([ S, T ] ) ;
Testit ([ P1, P2 ] );
Testit ([ @testit, Nil ] );
Testit ([ ObjA, ObjB ] );
Testit ([ 1.234, 1.234 ] );
TestIt ([ AClass ] );
```

If the procedure is declared with the `cdecl` modifier, then the compiler will pass the array as a C compiler would pass it. This, in effect, emulates the C construct of a variable number of arguments, as the following example will show:

```
program testaocc;
{$mode objfpc}

Const
  P : PChar = 'example';
  Fmt : PChar =
    'This %s uses printf to print numbers (%d) and strings.'#10;

// Declaration of standard C function printf:
procedure printf (fm : pchar; args : array of const);cdecl; external 'c';

begin
  printf(Fmt, [P, 123]);
end.
```

Remark that this is not true for Delphi, so code relying on this feature will not be portable.

## 14.5 Function overloading

Function overloading simply means that the same function is defined more than once, but each time with a different formal parameter list. The parameter lists must differ at least in one of its elements type. When the compiler encounters a function call, it will look at the function parameters to decide which one of the defined functions it should call. This can be useful when the same function must be defined for different types. For example, in the RTL, the `Dec` procedure could be defined as:

```
...
Dec (Var I : Longint; decrement : Longint);
Dec (Var I : Longint);
Dec (Var I : Byte; decrement : Longint);
Dec (Var I : Byte);
...
```

When the compiler encounters a call to the `Dec` function, it will first search which function it should use. It therefore checks the parameters in a function call, and looks if there is a function definition which matches the specified parameter list. If the compiler finds such a function, a call is inserted to that function. If no such function is found, a compiler error is generated.

Functions that have a `cdecl` modifier cannot be overloaded. (Technically, because this modifier prevents the mangling of the function name by the compiler).

Prior to version 1.9 of the compiler, the overloaded functions needed to be in the same unit. Now the compiler will continue searching in other units if it doesn't find a matching version of an overloaded function in one unit, and if the `overload` keyword is present.

If the `overload` keyword is not present, then all overloaded versions must reside in the same unit, and if it concerns methods part of a class, they must be in the same class, i.e. the compiler will not look for overloaded methods in parent classes if the `overload` keyword was not specified.

## 14.6 Forward declared functions

A function can be declared without having it followed by its implementation, by having it followed by the `forward` procedure. The effective implementation of that function must follow later in the module. The function can be used after a `forward` declaration as if it had been implemented already. The following is an example of a forward declaration.

```
Program testforward;
Procedure First (n : longint); forward;
Procedure Second;
begin
    WriteLn ('In second. Calling first...');
    First (1);
end;
Procedure First (n : longint);
begin
    WriteLn ('First received : ',n);
end;
begin
    Second;
end.
```

A function can be forward declared only once. Likewise, in units, it is not allowed to have a forward declared function of a function that has been declared in the interface part. The interface declaration counts as a `forward` declaration. The following unit will give an error when compiled:

```
Unit testforward;
interface
Procedure First (n : longint);
Procedure Second;
implementation
Procedure First (n : longint); forward;
Procedure Second;
begin
    WriteLn ('In second. Calling first...');
    First (1);
end;
Procedure First (n : longint);
begin
    WriteLn ('First received : ',n);
end;
end.
```

Reversely, functions declared in the interface section cannot be declared forward in the implementation section. Logically, since they already have been declared.

## 14.7 External functions

The `external` modifier can be used to declare a function that resides in an external object file. It allows to use the function in some code, and at linking time, the object file containing the implementation of the function or procedure must be linked in.

It replaces, in effect, the function or procedure code block. As an example:

```

program CmodDemo;
{$Linklib c}
Const P : PChar = 'This is fun !';
Function strlen (P : PChar) : Longint; cdecl; external;
begin
  WriteLn ('Length of (' , p , ') : ' , strlen(p))
end.
  
```

**Remark:** The parameters in the declaration of the `external` function should match exactly the ones in the declaration in the object file.

If the `external` modifier is followed by a string constant:

```
external 'lname';
```

Then this tells the compiler that the function resides in library `'lname'`. The compiler will then automatically link this library to the program.

The name that the function has in the library can also be specified:

```
external 'lname' name 'Fname';
```

This tells the compiler that the function resides in library `'lname'`, but with name `'Fname'`. The compiler will then automatically link this library to the program, and use the correct name for the function. Under WINDOWS and OS/2, the following form can also be used:

```
external 'lname' Index Ind;
```

This tells the compiler that the function resides in library `'lname'`, but with index `Ind`. The compiler will then automatically link this library to the program, and use the correct index for the function.

Finally, the `external` directive can be used to specify the external name of the function :

```
external name 'Fname';
{$L myfunc.o}
```

This tells the compiler that the function has the name `'Fname'`. The correct library or object file (in this case `myfunc.o`) must still be linked, ensuring that the function `'Fname'` is indeed included in the linking stage.

### 14.9.1 alias

The `alias` modifier allows the programmer to specify a different name for a procedure or function. This is mostly useful for referring to this procedure from assembly language constructs or from another object file. As an example, consider the following program:

```
Program Aliases;

Procedure Printit; alias : 'DOIT';
begin
    WriteLn ('In Printit (alias : "DOIT")');
end;
begin
    asm
        call DOIT
    end;
end.
```

**Remark:** The specified alias is inserted straight into the assembly code, thus it is case sensitive.

The `alias` modifier does not make the symbol public to other modules, unless the routine is also declared in the interface part of a unit, or the `public` modifier is used to force it as public. Consider the following:

```
unit testalias;

interface

procedure testroutine;

implementation

procedure testroutine; alias: 'ARoutine';
begin
    WriteLn('Hello world');
end;

end.
```

This will make the routine `testroutine` available publicly to external object files under the label name `ARoutine`.

**Remark:** The `alias` directive is considered deprecated. Please use the `public name` directive. See section [14.9.12](#), page 182.

### 14.9.2 cdecl

The `cdecl` modifier can be used to declare a function that uses a C type calling convention. This must be used when accessing functions residing in an object file generated by standard C compilers, but must also be used for Pascal functions that are to be used as callbacks for C libraries.

The `cdecl` modifier allows to use C function in the code. For external C functions, the object file containing the C implementation of the function or procedure must be linked in. As an example:

```
program CmodDemo;
```

```
{ $LINKLIB c }
Const P : PChar = 'This is fun !';
Function StrLen(P: PChar): Longint; cdecl; external name 'strlen';
begin
    WriteLn ('Length of (' , p, ') : ' , StrLen(p));
end.
```

When compiling this, and linking to the C-library, the `strlen` function can be called throughout the program. The `external` directive tells the compiler that the function resides in an external object file or library with the 'strlen' name (see 14.7).

**Remark:** The parameters in our declaration of the C function should match exactly the ones in the declaration in C.

For functions that are not external, but which are declared using `cdecl`, no external linking is needed. These functions have some restrictions, for instance the `array of const` construct can not be used (due the way this uses the stack). On the other hand, the `cdecl` modifier allows these functions to be used as callbacks for routines written in C, as the latter expect the 'cdecl' calling convention.

### 14.9.3 export

The `export` modifier is used to export names when creating a shared library or an executable program. This means that the symbol will be publicly available, and can be imported from other programs. For more information on this modifier, consult the section on “Making libraries” in the [Programmer's Guide](#).

### 14.9.4 inline

Procedures that are declared `inline` are copied to the places where they are called. This has the effect that there is no actual procedure call, the code of the procedure is just copied to where the procedure is needed, this results in faster execution speed if the function or procedure is used a lot. It is obvious that inlining large functions does not make sense.

By default, `inline` procedures are not allowed. Inline code must be enabled using the command-line switch `-Si` or `{ $inline on }` directive.

**Remark:**

1. `inline` is only a hint for the compiler. This does *not* automatically mean that all calls are inlined; sometimes the compiler may decide that a function simply cannot be inlined, or that a particular call to the function cannot be inlined. If so, the compiler will emit a warning.
2. In old versions of Free Pascal, inline code was *not* exported from a unit. This meant that when calling an inline procedure from another unit, a normal procedure call will be performed. Only inside units, `Inline` procedures are really inlined. As of version 2.0.2, inline works accross units.
3. Recursive inline functions are not allowed. i.e. an inline function that calls itself is not allowed.

### 14.9.5 interrupt

The `interrupt` keyword is used to declare a routine which will be used as an interrupt handler. On entry to this routine, all the registers will be saved and on exit, all registers will be restored and an interrupt or trap return will be executed (instead of the normal return from subroutine instruction).

On platforms where a return from interrupt does not exist, the normal exit code of routines will be done instead. For more information on the generated code, consult the [Programmer's Guide](#).

### 14.9.6 `iocheck`

The `iocheck` keyword is used to declare a routine which causes generation of I/O result checking code within a `{ $IOCHECKS ON }` block whenever it is called.

The result is that if a call to this procedure is generated, the compiler will insert I/O checking code if the call is within a `{ $IOCHECKS ON }` block.

This modifier is intended for RTL internal routines, not for use in application code.

### 14.9.7 `local`

The `local` modifier allows the compiler to optimize the function: a local function cannot be in the interface section of a unit: it is always in the implementation section of the unit. From this it follows that the function cannot be exported from a library.

On Linux, the `local` directive results in some optimizations. On Windows, it has no effect. It was introduced for Kylix compatibility.

### 14.9.8 `noreturn`

The `noreturn` modifier can be used to tell the compiler the procedure does not return. This information can be used by the compiler to avoid emitting warnings about uninitialized variables or results not being set.

In the following example, the compiler will not emit a warning that the result may not be set in function `f`:

```
procedure do_halt;noreturn;
begin
  halt(1);
end;

function f(i : integer) : integer ;

begin
  if (i<0) then
    do_halt
  else
    result:=i;
end;
```

### 14.9.9 `nostackframe`

The `nostackframe` modifier can be used to tell the compiler it should not generate a stack frame for this procedure or function. By default, a stack frame is always generated for each procedure or function.

One should be extremely careful when using this modifier: most procedures or functions need a stack frame. Particularly for debugging they are needed.

### 14.9.10 overload

The `overload` modifier tells the compiler that this function is overloaded. It is mainly for Delphi compatibility, as in Free Pascal, all functions and procedures can be overloaded without this modifier.

There is only one case where the `overload` modifier is mandatory: if a function must be overloaded that resides in another unit. Both functions must be declared with the `overload` modifier: the `overload` modifier tells the compiler that it should continue looking for overloaded versions in other units.

The following example illustrates this. Take the first unit:

```
unit ua;

interface

procedure DoIt(A : String); overload;

implementation

procedure DoIt(A : String);

begin
    Writeln('ua.DoIt received ',A)
end;

end.
```

And a second unit, which contains an overloaded version:

```
unit ub;

interface

procedure DoIt(A : Integer); overload;

implementation

procedure DoIt(A : integer);

begin
    Writeln('ub.DoIt received ',A)
end;

end.
```

And the following program, which uses both units:

```
program uab;

uses ua,ub;

begin
    DoIt('Some string');
end.
```

When the compiler starts looking for the declaration of `DoIt`, it will find one in the `ub` unit. Without the `overload` directive, the compiler would give an argument mismatch error:

```
home: >fpc uab.pp
uab.pp(6,21) Error: Incompatible type for arg no. 1:
Got "Constant String", expected "SmallInt"
```

With the `overload` directive in place at both locations, the compiler knows it must continue searching for an overloaded version with matching parameter list. Note that *both* declarations must have the `overload` modifier specified; it is not enough to have the modifier in unit `ub`. This is to prevent unwanted overloading: the programmer who implemented the `ua` unit must mark the procedure as fit for overloading.

### 14.9.11 pascal

The `pascal` modifier can be used to declare a function that uses the classic Pascal type calling convention (passing parameters from left to right). For more information on the Pascal calling convention, consult the [Programmer's Guide](#).

### 14.9.12 public

The `Public` keyword is used to declare a function globally in a unit. This is useful if the function should not be accessible from the unit file (i.e. another unit/program using the unit doesn't see the function), but must be accessible from the object file. As an example:

```
Unit someunit;
interface
Function First : Real;
Implementation
Function First : Real;
begin
    First := 0;
end;
Function Second : Real; [Public];
begin
    Second := 1;
end;
end.
```

If another program or unit uses this unit, it will not be able to use the function `Second`, since it isn't declared in the interface part. However, it will be possible to access the function `Second` at the assembly-language level, by using its mangled name (see the [Programmer's Guide](#)).

The `public` modifier can also be followed by a name directive to specify the assembler name, as follows:

```
Unit someunit;
interface
Function First : Real;
Implementation
Function First : Real;
begin
    First := 0;
end;
```

```
Function Second : Real; Public name 'second';  
begin  
    Second := 1;  
end;  
end.
```

The assembler symbol as specified by the 'public name' directive will be 'second', in all lowercase letters.

### 14.9.13 register

The `register` keyword is used for compatibility with Delphi. In version 1.0.x of the compiler, this directive has no effect on the generated code. As of the 1.9.X versions, this directive is supported. The first three arguments are passed in registers EAX,ECX and EDX.

### 14.9.14 safecall

The `safecall` modifier resembles closely the `stdcall` modifier. It sends parameters from right to left on the stack. Additionally, the called procedure saves and restores all registers.

More information about this modifier can be found in the [Programmer's Guide](#), in the section on the calling mechanism and the chapter on linking.

### 14.9.15 saveregisters

The `saveregisters` modifier tells the compiler that all CPU registers should be saved prior to calling this routine. Which CPU registers are saved, depends entirely on the CPU.

### 14.9.16 softfloat

The `softfloat` modifier makes sense only on the ARM architecture.

### 14.9.17 stdcall

The `stdcall` modifier pushes the parameters from right to left on the stack, it also aligns all the parameters to a default alignment.

More information about this modifier can be found in the [Programmer's Guide](#), in the section on the calling mechanism and the chapter on linking.

### 14.9.18 varargs

This modifier can only be used together with the `cdecl` modifier, for external C procedures. It indicates that the procedure accepts a variable number of arguments after the last declared variable. These arguments are passed on without any type checking. It is equivalent to using the `array of const` construction for `cdecl` procedures, without having to declare the `array of const`. The square brackets around the variable arguments do not need to be used when this form of declaration is used.

The following declarations are 2 ways of referring to the same function in the C library:

```
Function PrintF1(fmt : pchar); cdecl; varargs;
```

```
external 'c' name 'printf';  
Function PrintF2(fmt : pchar; Args : Array of const); cdecl;  
external 'c' name 'printf';
```

But they must be called differently:

```
PrintF1 ('%d %d\n', 1, 1);  
PrintF2 ('%d %d\n', [1, 1]);
```

## 14.10 Unsupported Turbo Pascal modifiers

The modifiers that exist in Turbo Pascal, but aren't supported by Free Pascal, are listed in table [\(14.1\)](#).

Table 14.1: Unsupported modifiers

Modifier	Why not supported ?
Near	Free Pascal is a 32-bit compiler.
Far	Free Pascal is a 32-bit compiler.

The compiler will give a warning when it encounters these modifiers, but will otherwise completely ignore them.

## Chapter 15

# Operator overloading

### 15.1 Introduction

Free Pascal supports operator overloading. This means that it is possible to define the action of some operators on self-defined types, and thus allow the use of these types in mathematical expressions.

Defining the action of an operator is much like the definition of a function or procedure, only there are some restrictions on the possible definitions, as will be shown in the subsequent.

Operator overloading is, in essence, a powerful notational tool; but it is also not more than that, since the same results can be obtained with regular function calls. When using operator overloading, it is important to keep in mind that some implicit rules may produce some unexpected results. This will be indicated.

### 15.2 Operator declarations

To define the action of an operator is much like defining a function:

The parameter list for a comparison operator or an arithmetic operator must always contain 2 parameters, with the exception of the unary minus, where only 1 parameter is needed. The result type of the comparison operator must be Boolean.

**Remark:** When compiling in Delphi mode or Objfpc mode, the result identifier may be dropped. The result can then be accessed through the standard `Result` symbol.

If the result identifier is dropped and the compiler is not in one of these modes, a syntax error will occur.

The statement block contains the necessary statements to determine the result of the operation. It can contain arbitrary large pieces of code; it is executed whenever the operation is encountered in some expression. The result of the statement block must always be defined; error conditions are not checked by the compiler, and the code must take care of all possible cases, throwing a run-time error if some error condition is encountered.

In the following, the three types of operator definitions will be examined. As an example, throughout this chapter the following type will be used to define overloaded operators on :

```

type
  complex = record
    re : real;
    im : real;
  end;
  
```

This type will be used in all examples.

The sources of the Run-Time Library contain 2 units that heavily use operator overloading:

**ucomplex** This unit contains a complete calculus for complex numbers.

**matrix** This unit contains a complete calculus for matrices.

### 15.3 Assignment operators

The assignment operator defines the action of an assignment of one type of variable to another. The result type must match the type of the variable at the left of the assignment statement, the single parameter to the assignment operator must have the same type as the expression at the right of the assignment operator.

This system can be used to declare a new type, and define an assignment for that type. For instance, to be able to assign a newly defined type 'Complex'

```

Var
  C, Z : Complex; // New type complex

begin
  Z:=C; // assignments between complex types.
end;
  
```

The following assignment operator would have to be defined:

```
Operator := (C : Complex) z : complex;
```

To be able to assign a real type to a complex type as follows:

```
var
  R : real;
  C : complex;

begin
  C:=R;
end;
```

the following assignment operator must be defined:

```
Operator := (r : real) z : complex;
```

As can be seen from this statement, it defines the action of the operator := with at the right a real expression, and at the left a complex expression.

An example implementation of this could be as follows:

```
operator := (r : real) z : complex;

begin
  z.re:=r;
  z.im:=0.0;
end;
```

As can be seen in the example, the result identifier (z in this case) is used to store the result of the assignment. When compiling in Delphi mode or ObjFPC mode, the use of the special identifier Result is also allowed, and can be substituted for the z, so the above would be equivalent to

```
operator := (r : real) z : complex;

begin
  Result.re:=r;
  Result.im:=0.0;
end;
```

The assignment operator is also used to convert types from one type to another. The compiler will consider all overloaded assignment operators till it finds one that matches the types of the left hand and right hand expressions. If no such operator is found, a 'type mismatch' error is given.

**Remark:** The assignment operator is not commutative; the compiler will never reverse the role of the two arguments. In other words, given the above definition of the assignment operator, the following is *not* possible:

```
var
  R : real;
  C : complex;

begin
  R:=C;
end;
```

If the reverse assignment should be possible then the assignment operator must be defined for that as well. (This is not so for reals and complex numbers.)

**Remark:** The assignment operator is also used in implicit type conversions. This can have unwanted effects. Consider the following definitions:

```
operator := (r : real) z : complex;  
function exp(c : complex) : complex;
```

Then the following assignment will give a type mismatch:

```
Var  
  r1, r2 : real;  
  
begin  
  r1:=exp(r2);  
end;
```

The mismatch occurs because the compiler will encounter the definition of the `exp` function with the complex argument. It implicitly converts `r2` to a complex, so it can use the above `exp` function. The result of this function is a complex, which cannot be assigned to `r1`, so the compiler will give a 'type mismatch' error. The compiler will not look further for another `exp` which has the correct arguments.

It is possible to avoid this particular problem by specifying

```
r1:=system.exp(r2);
```

When doing an explicit typecast, the compiler will attempt an implicit conversion if an assignment operator is present. That means that

```
Var  
  R1 : T1;  
  R2 : T2;  
  
begin  
  R2:=T2(R1);
```

Will be handled by an operator

```
Operator := (aRight: T1) Res: T2;  
\begin{verbatim}
```

However, an `\var{Explicit}` operator can be defined, and then it will be used instead when the compiler encounters a typecast.

The reverse is not true: In a regular assignment, the compiler will not consider explicit assignment operators.

Given the following definitions:

```
\begin{verbatim}  
uses  
  sysutils;  
  
type  
  TTest1 = record
```

```
    f: LongInt;
end;
TTest2 = record
    f: String;
end;
TTest3 = record
    f: Boolean;
end;
```

It is possible to create assignment operators:

```
operator := (aRight: TTest1) Res: TTest2;
begin
    Writeln('Implicit TTest1 => TTest2');
    Res.f := IntToStr(aRight.f);
end;
```

```
operator := (aRight: TTest1) Res: TTest3;
begin
    Writeln('Implicit TTest1 => TTest3');
    Res.f := aRight.f <> 0;
end;
```

But one can also define typecasting operators:

```
operator Explicit(aRight: TTest2) Res: TTest1;
begin
    Writeln('Explicit TTest2 => TTest1');
    Res.f := StrToIntDef(aRight.f, 0);
end;
```

```
operator Explicit(aRight: TTest1) Res: TTest3;
begin
    Writeln('Explicit TTest1 => TTest3');
    Res.f := aRight.f <> 0;
end;
```

Thus, the following code

```
var
    t1: TTest1;
    t2: TTest2;
    t3: TTest3;
begin
    t1.f := 42;
    // Implicit
    t2 := t1;
    // theoretically explicit, but implicit op will be used,
    // because no explicit operator is defined
    t2 := TTest2(t1);
    // the following would not compile,
    // no assignment operator defined (explicit one won't be used here)
    //t1 := t2;
    // Explicit
```

```

t1 := TTest1(t2);
// first explicit (TTest2 => TTest1) then implicit (TTest1 => TTest3)
t3 := TTest1(t2);
// Implicit
t3 := t1;
// explicit
t3 := TTest3(t1);
end.

```

will produce the following output:

```

Implicit TTest1 => TTest2
Implicit TTest1 => TTest2
Explicit TTest2 => TTest1
Explicit TTest2 => TTest1
Implicit TTest1 => TTest3
Implicit TTest1 => TTest3
Explicit TTest1 => TTest3

```

## 15.4 Arithmetic operators

Arithmetic operators define the action of a binary operator. Possible operations are:

**multiplication** To multiply two types, the `*` multiplication operator must be overloaded.

**division** To divide two types, the `/` division operator must be overloaded.

**addition** To add two types, the `+` addition operator must be overloaded.

**subtraction** To subtract two types, the `-` subtraction operator must be overloaded.

**exponentiation** To exponentiate two types, the `**` exponentiation operator must be overloaded.

**Unary minus** is used to take the negative of the argument following it.

**Symmetric Difference** To take the symmetric difference of 2 structures, the `><` operator must be overloaded.

The definition of an arithmetic operator takes two parameters, except for unary minus, which needs only 1 parameter. The first parameter must be of the type that occurs at the left of the operator, the second parameter must be of the type that is at the right of the arithmetic operator. The result type must match the type that results after the arithmetic operation.

To compile an expression as

```

var
  R : real;
  C, Z : complex;

begin
  C := R * Z;
end;

```

One needs a definition of the multiplication operator as:

```

Operator * (r : real; z1 : complex) z : complex;

begin
  z.re := z1.re * r;
  z.im := z1.im * r;
end;

```

As can be seen, the first operator is a real, and the second is a complex. The result type is complex.

Multiplication and addition of reals and complexes are commutative operations. The compiler, however, has no notion of this fact so even if a multiplication between a real and a complex is defined, the compiler will not use that definition when it encounters a complex and a real (in that order). It is necessary to define both operations.

So, given the above definition of the multiplication, the compiler will not accept the following statement:

```

var
  R : real;
  C, Z : complex;

begin
  C := Z * R;
end;

```

Since the types of Z and R don't match the types in the operator definition.

The reason for this behaviour is that it is possible that a multiplication is not always commutative. E.g. the multiplication of a  $(n, m)$  with a  $(m, n)$  matrix will result in a  $(n, n)$  matrix, while the multiplication of a  $(m, n)$  with a  $(n, m)$  matrix is a  $(m, m)$  matrix, which needn't be the same in all cases.

## 15.5 Comparison operator

The comparison operator can be overloaded to compare two different types or to compare two equal types that are not basic types. The result type of a comparison operator is always a boolean.

The comparison operators that can be overloaded are:

**equal to** (=) To determine if two variables are equal.

**unequal to** (<>) To determine if two variables are different.

**less than** (<) To determine if one variable is less than another.

**greater than** (>) To determine if one variable is greater than another.

**greater than or equal to** (>=) To determine if one variable is greater than or equal to another.

**less than or equal to** (<=) To determine if one variable is greater than or equal to another.

If there is no separate operator for *unequal to* (<>), then, to evaluate a statement that contains the *unequal to* operator, the compiler uses the *equal to* operator (=), and negates the result. The opposite is not true: if no "equal to" but an "unequal to" operator exists, the compiler will not use it to evaluate an expression containing the equal (=) operator.

As an example, the following operator allows to compare two complex numbers:

```
operator = (z1, z2 : complex) b : boolean;
```

the above definition allows comparisons of the following form:

```
Var
  C1,C2 : Complex;

begin
  If C1=C2 then
    Writeln('C1 and C2 are equal');
end;
```

The comparison operator definition needs 2 parameters, with the types that the operator is meant to compare. Here also, the compiler doesn't apply commutativity: if the two types are different, then it is necessary to define 2 comparison operators.

In the case of complex numbers, it is, for instance necessary to define 2 comparisons: one with the complex type first, and one with the real type first.

Given the definitions

```
operator = (z1 : complex;r : real) b : boolean;
operator = (r : real; z1 : complex) b : boolean;
```

the following two comparisons are possible:

```
Var
  R,S : Real;
  C : Complex;

begin
  If (C=R) or (S=C) then
    Writeln ('Ok');
end;
```

Note that the order of the real and complex type in the two comparisons is reversed.

## 15.6 In operator

As of version 2.6 of Free pascal, the `In` operator can be overloaded as well. The first argument of the `in` operator must be the operand on the left of the `in` keyword. The following overloads the `in` operator for records:

```
{ $mode objfpc } { $H+ }

type
  TMyRec = record A: Integer end;

operator in (const A: Integer; const B: TMyRec): boolean;
begin
  Result := A = B.A;
end;
```

```
var
  R: TMyRec;
begin
  R.A := 10;
  Writeln(1 in R); // false
  Writeln(10 in R); // true
end.
```

The `in` operator can also be overloaded for other types than ordinal types, as in the following example:

```
{ $mode objfpc } { $H+ }

type
  TMyRec = record A: Integer end;

operator in (const A: TMyRec; const B: TMyRec): boolean;
begin
  Result := A.A = B.A;
end;

var
  S, R: TMyRec;
begin
  R.A := 10;
  S.A:=1;
  Writeln(S in R); // false
  Writeln(R in R); // true
end.
```

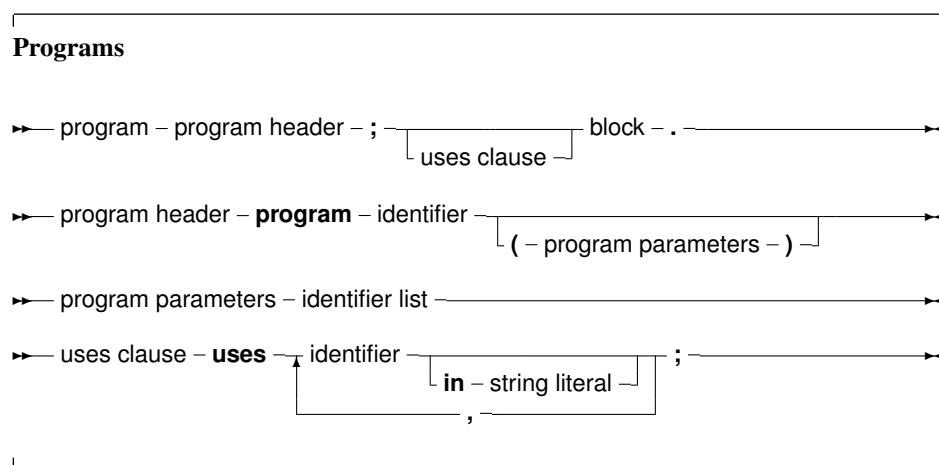

## Chapter 16

# Programs, units, blocks

A Pascal program can consist of modules called `units`. A unit can be used to group pieces of code together, or to give someone code without giving the sources. Both programs and units consist of code blocks, which are mixtures of statements, procedures, and variable or type declarations.

### 16.1 Programs

A Pascal program consists of the program header, followed possibly by a 'uses' clause, and a block.

The program header is provided for backwards compatibility, and is ignored by the compiler.

The uses clause serves to identify all units that are needed by the program. All identifiers which are declared in the interface section of the units in the uses clause are added to the known identifiers of the program. The system unit doesn't have to be in this list, since it is always loaded by the compiler.

The order in which the units appear is significant, it determines in which order they are initialized. Units are initialized in the same order as they appear in the uses clause. Identifiers are searched in the opposite order, i.e. when the compiler searches for an identifier, then it looks first in the last unit in the uses clause, then the last but one, and so on. This is important in case two units declare different types with the same identifier.

The compiler will look for compiled versions or source versions of all units in the uses clause in the unit search path. If the unit filename was explicitly mentioned using the `in` keyword, the source is taken from the filename specified:

```
program programb;

uses unita in '..\unita.ppu';
```

`unita` is searched in the parent directory of the `programb` source file.

When the compiler looks for unit files, it adds the extension `.ppu` to the name of the unit. On LINUX and in operating systems where filenames are case sensitive when looking for a unit, the following mechanism is used:

1. The unit is first looked for in the original case.
2. The unit is looked for in all-lowercase letters.
3. The unit is looked for in all-uppercase letters.

Additionally, If a unit name is longer than 8 characters, the compiler will first look for a unit name with this length, and then it will truncate the name to 8 characters and look for it again. For compatibility reasons, this is also true on platforms that support long file names.

Note that the above search is performed in each directory in the search path.

The program block contains the statements that will be executed when the program is started. Note that these statements need not necessarily be the first statements that are executed: the initialization code of the units may also contain statements that are executed prior to the program code.

The structure of a program block is discussed below.

## 16.2 Units

A unit contains a set of declarations, procedures and functions that can be used by a program or another unit. The syntax for a unit is as follows:

As can be seen from the syntax diagram, a unit always consists of a interface and an implementation part. Optionally, there is an initialization block and a finalization block, containing code that will be executed when the program is started, and when the program stops, respectively.

Both the interface part or implementation part can be empty, but the keywords `Interface` and `implementation` must be specified. The following is a completely valid unit;

```

unit a;

interface

implementation

end.
  
```

The interface part declares all identifiers that must be exported from the unit. This can be constant, type or variable identifiers, and also procedure or function identifier declarations. The interface part cannot contain code that is executed: only declarations are allowed. The following is a valid interface part:

```

unit a;

interface

uses b;

Function MyFunction : SomeBType;

Implementation
  
```

The type `SomeBType` is defined in unit `b`.

All functions and methods that are declared in the interface part must be implemented in the implementation part of the unit, except for declarations of external functions or procedures. If a declared method or function is not implemented in the implementation part, the compiler will give an error, for example the following:

```

unit unita;

interface

Function MyFunction : Integer;

implementation

end.
  
```

Will result in the following error:

```
unitA.pp(5,10) Error: Forward declaration not solved "MyFunction:SmallInt;"
```

The implementation part is primarily intended for the implementation of the functions and procedures declared in the interface part. However, it can also contain declarations of its own: the declarations inside the implementation part are *not* accessible outside the unit.

The initialization and finalization part of a unit are optional.

The initialization block is used to initialize certain variables or execute code that is necessary for the correct functioning of the unit. The initialization parts of the units are executed in the order that the compiler loaded the units when compiling a program. They are executed before the first statement of the program is executed.

The finalization part of the units are executed in the reverse order of the initialization execution. They are used for instance to clean up any resources allocated in the initialization part of the unit, or during the lifetime of the program. The finalization part is always executed in the case of a normal program termination: whether it is because the final `end` is reached in the program code or because a `Halt` instruction was executed somewhere.

In case the program stops during the execution of the initialization blocks of one of the units, only the units that were already initialized will be finalized. Note that in difference with Delphi, in Free Pascal a `finalization` block can be present without an `Initialization` block. That means the following will compile in Free Pascal, but not in Delphi.

```
Finalization
  CleanupUnit;
end.
```

An initialization section by itself (i.e. without finalization) may simply be replaced by a statement block. That is, the following:

```
Initialization
  InitializeUnit;
end.
```

is completely equivalent to

```
Begin
  InitializeUnit;
end.
```

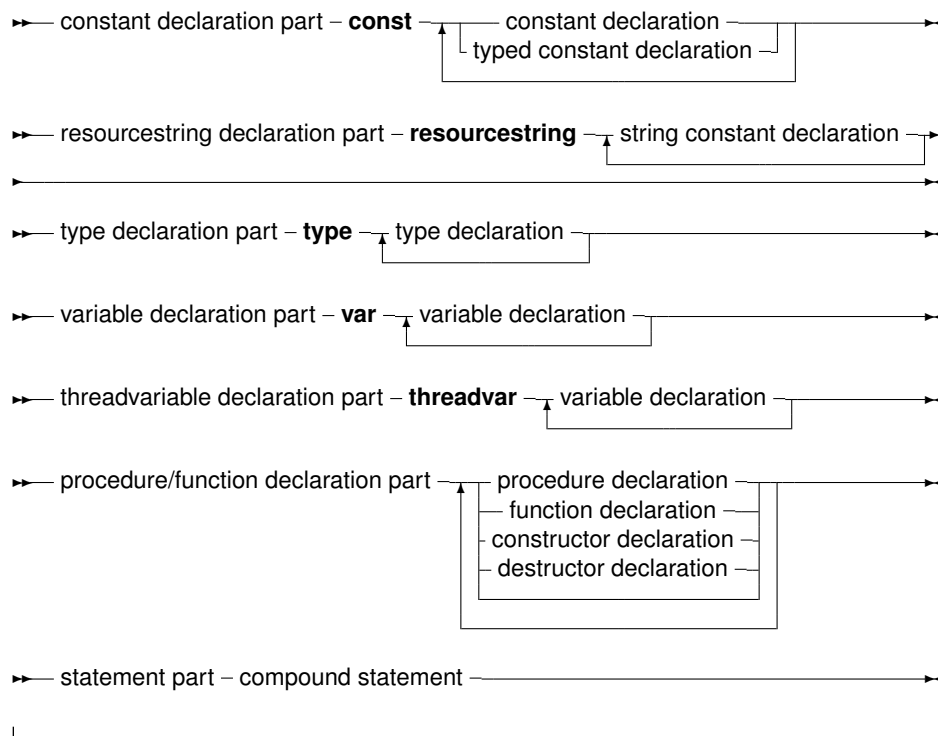

## 16.3 Unit dependencies

When a program uses a unit (say `unitA`) and this unit uses a second unit, say `unitB`, then the program depends indirectly also on `unitB`. This means that the compiler must have access to `unitB` when trying to compile the program. If the unit is not present at compile time, an error occurs.

Note that the identifiers from a unit on which a program depends indirectly, are not accessible to the program. To have access to the identifiers of a unit, the unit must be in the `uses` clause of the program or unit where the identifiers are needed.

Units can be mutually dependent, that is, they can reference each other in their `uses` clauses. This is allowed, on the condition that at least one of the references is in the implementation section of the unit. This also holds for indirect mutually dependent units.

Labels that can be used to identify statements in a block are declared in the label declaration part of that block. Each label can only identify one statement.

Constants that are to be used only in one block should be declared in that block's constant declaration part.

Variables that are to be used only in one block should be declared in that block's variable declaration part.

Types that are to be used only in one block should be declared in that block's type declaration part.

Lastly, functions and procedures that will be used in that block can be declared in the procedure/-function declaration part.

These 4 declaration parts can be intermixed, there is no required order other than that you cannot use (or refer to) identifiers that have not yet been declared.

After the different declaration parts comes the statement part. This contains any actions that the block should execute. All identifiers declared before the statement part can be used in that statement part.

## 16.5 Scope

Identifiers are valid from the point of their declaration until the end of the block in which the declaration occurred. The range where the identifier is known is the *scope* of the identifier. The exact scope of an identifier depends on the way it was defined.

### 16.5.1 Block scope

The *scope* of a variable declared in the declaration part of a block, is valid from the point of declaration until the end of the block. If a block contains a second block, in which the identifier is redeclared, then inside this block, the second declaration will be valid. Upon leaving the inner block, the first declaration is valid again. Consider the following example:

```
Program Demo;
Var X : Real;
{ X is real variable }
Procedure NewDeclaration
Var X : Integer; { Redeclare X as integer}
begin
  // X := 1.234; {would give an error when trying to compile}
  X := 10; { Correct assignment}
end;
{ From here on, X is Real again}
begin
  X := 2.468;
end.
```

In this example, inside the procedure, `X` denotes an integer variable. It has its own storage space, independent of the variable `X` outside the procedure.

### 16.5.2 Record scope

The field identifiers inside a record definition are valid in the following places:

1. To the end of the record definition.
2. Field designators of a variable of the given record type.
3. Identifiers inside a `With` statement that operates on a variable of the given record type.

### 16.5.3 Class scope

A component identifier (one of the items in the class' component list) is valid in the following places:

1. From the point of declaration to the end of the class definition.
2. In all descendent types of this class, unless it is in the private part of the class declaration.
3. In all method declaration blocks of this class and descendent classes.
4. In a `With` statement that operators on a variable of the given class's definition.

Note that method designators are also considered identifiers.

### 16.5.4 Unit scope

All identifiers in the interface part of a unit are valid from the point of declaration, until the end of the unit. Furthermore, the identifiers are known in programs or units that have the unit in their uses clause.

Identifiers from indirectly dependent units are *not* available. Identifiers declared in the implementation part of a unit are valid from the point of declaration to the end of the unit.

The **system** unit is automatically used in all units and programs. Its identifiers are therefore always known, in each Pascal program, library or unit.

The rules of unit scope imply that an identifier of a unit can be redefined. To have access to an identifier of another unit that was redeclared in the current unit, precede it with that other units name, as in the following example:

```

unit unitA;
interface
Type
  MyType = Real;
implementation
end.
Program prog;
Uses UnitA;

{ Redeclaration of MyType }
Type MyType = Integer;
Var A : Mytype;      { Will be Integer }
    B : UnitA.MyType { Will be real }
begin
end.

```

This is especially useful when redeclaring the system unit's identifiers.

## 16.6 Libraries

Free Pascal supports making of dynamic libraries (DLLs under Win32 and OS/2) through the use of the `Library` keyword.

A Library is just like a unit or a program:

### Libraries

→ library – library header – ; ———— block – . ———→  
                                     └── uses clause ─┘

→ library header – **library** – identifier ———→

By default, functions and procedures that are declared and implemented in library are not available to a programmer that wishes to use this library.

In order to make functions or procedures available from the library, they must be exported in an exports clause:

### Exports clause

→ exports clause – **exports** – exports list – ; ———→

→ exports list — exports entry ———→  
                                     └── , ─┘

→ exports entry – identifier ———┐  
    └── **index** – integer constant ─┘ └── **name** – string constant ─┘

Under Win32, an index clause can be added to an exports entry. An index entry must be a positive number larger or equal than 1, and less than `MaxInt`.

Optionally, an exports entry can have a name specifier. If present, the name specifier gives the exact name (case sensitive) by which the function will be exported from the library.

If neither of these constructs is present, the functions or procedures are exported with the exact names as specified in the exports clause.

## Chapter 17

# Exceptions

Exceptions provide a convenient way to program error and error-recovery mechanisms, and are closely related to classes. Exception support is based on 3 constructs:

**Raise** statements. To raise an exception. This is usually done to signal an error condition. It is however also usable to abort execution and immediately return to a well-known point in the executable.

**Try ... Except** blocks. These block serve to catch exceptions raised within the scope of the block, and to provide exception-recovery code.

**Try ... Finally** blocks. These block serve to force code to be executed irrespective of an exception occurrence or not. They generally serve to clean up memory or close files in case an exception occurs. The compiler generates many implicit `Try ... Finally` blocks around procedure, to force memory consistency.

### 17.1 The raise statement

The `raise` statement is as follows:

This statement will raise an exception. If it is specified, the exception instance must be an initialized instance of any class, which is the raise type. The exception address and frame are optional. If they are not specified, the compiler will provide the address by itself. If the exception instance is omitted, then the current exception is re-raised. This construct can only be used in an exception handling block (see further).

**Remark:** Control *never* returns after an exception block. The control is transferred to the first `try ... finally` or `try ... except` statement that is encountered when unwinding the stack. If no such statement

is found, the Free Pascal Run-Time Library will generate a run-time error 217 (see also section 17.5, page 207). The exception address will be printed by the default exception handling routines.

As an example: The following division checks whether the denominator is zero, and if so, raises an exception of type `EDivException`

```
Type EDivException = Class(Exception);
Function DoDiv (X,Y : Longint) : Integer;
begin
  If Y=0 then
    Raise EDivException.Create ('Division by Zero would occur');
  Result := X Div Y;
end;
```

The class `Exception` is defined in the `Sysutils` unit of the rtl. (section 17.5, page 207)

**Remark:** Although the `Exception` class is used as the base class for exceptions throughout the code, this is just an unwritten agreement: the class can be of any type, and need not be a descendent of the `Exception` class.

Of course, most code depends on the unwritten agreement that an exception class descends from `Exception`.

The following code shows how to omit an error reporting routine from the stack shown in the exception handler:

```
{ $mode objfpc }
uses sysutils;

procedure error(Const msg : string);

begin
  raise exception.create(Msg) at
    get_caller_addr(get_frame),
    get_caller_frame(get_frame);
end;

procedure test2;

begin
  error('Error');
end;

begin
  test2;
end.
```

The program, when run, will show a backtrace as follows:

```
An unhandled exception occurred at $00000000004002D3 :
Exception : Error
  $00000000004002D3 line 15 of testme.pp
  $00000000004002E6 line 19 of testme.pp
```

Line 15 is in procedure `Test2`, not in `Error`, which actually raised the exception.

## 17.2 The try...except statement

A `try...except` exception handling block is of the following form :

If no exception is raised during the execution of the `statement list`, then all statements in the list will be executed sequentially, and the `except` block will be skipped, transferring program flow to the statement after the final `end`.

If an exception occurs during the execution of the `statement list`, the program flow will be transferred to the `except` block. Statements in the `statement list` between the place where the exception was raised and the `except` block are ignored.

In the exception handling block, the type of the exception is checked, and if there is an exception handler where the class type matches the exception object type, or is a parent type of the exception object type, then the statement following the corresponding `Do` will be executed. The first matching type is used. After the `Do` block was executed, the program continues after the `End` statement.

The identifier in an exception handling statement is optional, and declares an exception object. It can be used to manipulate the exception object in the exception handling code. The scope of this declaration is the statement block following the `Do` keyword.

If none of the `On` handlers matches the exception object type, then the `statement list` after `else` is executed. If no such list is found, then the exception is automatically re-raised. This process allows to nest `try...except` blocks.

If, on the other hand, the exception was caught, then the exception object is destroyed at the end of the exception handling block, before program flow continues. The exception is destroyed through a call to the object's `Destroy` destructor.

As an example, given the previous declaration of the `DoDiv` function, consider the following

```

Try
  Z := DoDiv (X,Y);
Except
  On EDivException do Z := 0;
end;

```

If `Y` happens to be zero, then the `DoDiv` function code will raise an exception. When this happens, program flow is transferred to the `except` statement, where the Exception handler will set the value of `Z` to zero. If no exception is raised, then program flow continues past the last `end` statement. To allow error recovery, the `Try ... Finally` block is supported. A `Try...Finally` block ensures that the statements following the `Finally` keyword are guaranteed to be executed, even if an exception occurs.

### 17.3 The try...finally statement

A Try...Finally statement has the following form:

#### Try...finally statement

→ trystatement – **try** – statement list – **finally** – finally statements – **end** →

→ finally statements – statementlist →

If no exception occurs inside the `statement List`, then the program runs as if the `Try`, `Finally` and `End` keywords were not present, unless an `exit` command is given: an `exit` command first executes all statements in the `finally` blocks before actually exiting.

If, however, an exception occurs, the program flow is immediately transferred from the point where the exception was raised to the first statement of the `Finally statements`.

All statements after the `finally` keyword will be executed, and then the exception will be automatically re-raised. Any statements between the place where the exception was raised and the first statement of the `Finally Statements` are skipped.

As an example consider the following routine:

```
Procedure Doit (Name : string);
Var F : Text;
begin
  Assign (F,Name);
  Rewrite (name);
  Try
    ... File handling ...
  Finally
    Close(F);
end;
```

If during the execution of the file handling an exception occurs, then program flow will continue at the `close(F)` statement, skipping any file operations that might follow between the place where the exception was raised, and the `Close` statement. If no exception occurred, all file operations will be executed, and the file will be closed at the end.

Note that an `Exit` statement enclosed by a `try ... finally` block, will still execute the `finally` block. Reusing the previous example:

```
Procedure Doit (Name : string);
Var
  F : Text;
  B : Boolean;
begin
  B:=False;
  Assign (F,Name);
  Rewrite (name);
  Try
    // ... File handling ...
    if B then
```

```
        exit; // Stop processing prematurely
    // More file handling
    Finally
        Close(F);
    end;
```

The file will still be closed, even if the processing ends prematurely using the `Exit` statement.

## 17.4 Exception handling nesting

It is possible to nest `Try...Except` blocks with `Try...Finally` blocks. Program flow will be done according to a `lifo` (last in, first out) principle: The code of the last encountered `Try...Except` or `Try...Finally` block will be executed first. If the exception is not caught, or it was a finally statement, program flow will be transferred to the last-but-one block, *ad infinitum*.

If an exception occurs, and there is no exception handler present which handles this exception, then a run-time error 217 will be generated. When using the `SysUtils` unit, a default handler is installed which will show the exception object message, and the address where the exception occurred, after which the program will exit with a `Halt` instruction.

## 17.5 Exception classes

The `sysutils` unit contains a great deal of exception handling. It defines the base exception class, `Exception`

```
Exception = class(TObject)
private
    fmessage : string;
    fhelppcontext : longint;
public
    constructor create(const msg : string);
    constructor createres(indent : longint);
    property helppcontext : longint read fhelppcontext write fhelppcontext;
    property message : string read fmessage write fmessage;
end;
ExceptionClass = Class of Exception;
```

And uses this declaration to define quite a number of exceptions, for instance:

```
{ mathematical exceptions }
EIntError = class(Exception);
EDivByZero = class(EIntError);
ERangeError = class(EIntError);
EIntOverflow = class(EIntError);
EMathError = class(Exception);
```

The `SysUtils` unit also installs an exception handler. If an exception is unhandled by any exception handling block, this handler is called by the Run-Time library. Basically, it prints the exception address, and it prints the message of the `Exception` object, and exits with an exit code of 217. If the exception object is not a descendant object of the `Exception` object, then the class name is printed instead of the exception message.

It is recommended to use the `Exception` object or a descendant class for all `raise` statements, since then the message field of the exception object can be used.

## Chapter 18

# Using assembler

Free Pascal supports the use of assembler in code, but not inline assembler macros. To have more information on the processor specific assembler syntax and its limitations, see the [Programmer's Guide](#).

### 18.1 Assembler statements

The following is an example of assembler inclusion in Pascal code.

```
...
Statements;
...
Asm
    the asm code here
    ...
end;
...
Statements;
```

The assembler instructions between the `Asm` and `end` keywords will be inserted in the assembler generated by the compiler. Conditionals can be used in assembler code, the compiler will recognise them, and treat them as any other conditionals.

### 18.2 Assembler procedures and functions

Assembler procedures and functions are declared using the `Assembler` directive. This permits the code generator to make a number of code generation optimizations.

The code generator does not generate any stack frame (entry and exit code for the routine) if it contains no local variables and no parameters. In the case of functions, ordinal values must be returned in the accumulator. In the case of floating point values, these depend on the target processor and emulation options.
